From Frege's Theorem, one can derive arithmetic. It is an immediate consequence of the functionality of Predecessor that every number has a unique successor. That means we can define the successor function:

$n' =_{df}$ the *x* such that *Precedes*(*n*,*x*)

We may then define the sequence of natural numbers succeeding 0 as follows:

$1 = 0'$
$2 = 1'$
$3 = 2'$
etc.

Moreover, the recursive definition of addition can now be given:

$n + 0 = n$
$n + m' = (n + m)'$

We may also officially define:

$n < m =_{\mathrm{df}} \mathit{Precedes}^*(n,m)$
$n \leq m =_{\mathrm{df}} \mathit{Precedes}^+(n,m)$

These definitions constitute the foundations of arithmetic. Frege has insightfully isolated a group of basic laws in which they may be grounded.

§6: Philosophical Questions Surrounding Frege's Theorem

Frege's Theorem is an elegant derivation of the basic laws of arithmetic which can be carried out independently of the portion of Frege's system which led to inconsistency. Frege himself never identified "Frege's Theorem" as a "result". In **Gg**, he attempted to derive Hume's Principle and the Dedekind-Peano axioms from Basic Law V, but once the contradiction became known to him, he never officially retreated to the ‘fall-back’ position of claiming that the proof of the Dedekind-Peano axioms from Hume's Principle alone constituted an important result. One of several reasons why he didn't adopt this fall-back position is that he didn't regard Hume's Principle as a sufficiently general principle---he didn't believe it was strong enough, from an epistemological point of view, to help us answer the question, "How are numbers given to us?". We discuss the reasons for his attitude, among other things, in what follows.

A discussion of the philosophical questions surrounding Frege's Theorem should begin with some statement of how Frege conceived of his own project when writing **Begr**, **Gl**, and **Gg**. It seems clear that epistemological considerations in part motivated Frege's work on the foundations of mathematics. It is well documented that Frege had the following goal, namely, to explain our knowledge of the basic laws of arithmetic by giving an answer to the question "How are numbers ‘given’ to us?" which makes no appeal to the faculty of intuition. If Frege could show that the basic laws of number theory are derivable from analytic truths of logic, then he could argue that we need only appeal to the faculty of understanding (as opposed to some faculty of intuition) to explain our knowledge of the truths of arithmetic. Frege's goal then stands in contrast to the Kantian view of the exact mathematical sciences, according to which general principles of reasoning must be supplemented by a faculty of intuition if we are to achieve mathematical knowledge. The Kantian model here is that of geometry; Kant thought that our intuitions of figures and constructions played an essential role in the demonstrations of geometrical theorems. (In Frege's own time, the achievements of Frege's contemporaries Pasch, Pieri and Hilbert showed that such intuitions were not essential.)

Frege's Goals and Strategy in His Own Words

Frege's strategy then was to show that no appeal to intuition is required for the derivation of the theorems of number theory. This in turn required that he show that the latter are derivable using only rules of inference, axioms, and definitions that are purely analytic principles of logic. This view has become known as ‘Logicism’. Here is what Frege says:

[**Begr**, Preface, p. 5:]
To prevent anything intuitive from penetrating here unnoticed, I had to bend every effort to keep the chain of inferences free of gaps.
[from the Bauer-Mengelberg translation in van Heijenoort (1967)]

[**Begr**, Part III, §23:]
Through the present example, moreover, we see how pure thought, irrespective of any content given by the senses or even by an intuition a priori, can, solely from the content that results from its own constitution, bring forth judgements that at first sight appear to be possible only on the basis of some intuition. ... The propositions about sequences [*R*-series] in what follows far surpass in generality all those that can be derived from any intuition of sequences.
[from the Bauer-Mengelberg translation in van Heijenoort (1967)]

[**Gl**, §62:]
How, then, are numbers to be given to us, if we cannot have any ideas or intuitions of them? Since it is only in the context of a proposition that words have any meaning, our problem becomes this: To define the sense of a proposition in which a number word occurs.
[from the Austin translation in Frege (1974)]

[**Gl**, §87:]
I hope I may claim in the present work to have made it probable that the laws of arithmetic are analytic judgements and consequently a priori. Arithmetic thus becomes simply a development of logic, and every proposition of arithmetic a law of logic, albeit a derivative one.
[from the Austin translation in Frege (1974)]

[**Gg I**, §0:]
In my *Grundlagen der Arithmetik*, I sought to make it plausible that arithmetic is a branch of logic and need not borrow any ground of proof whatever from either experience or intuition. In the present book, this shall be confirmed, by the derivation of the simplest laws of Numbers by logical means alone.
[from the Furth translation in Frege (1967)]

[**Gg II**, Appendix:]
The prime problem of arithmetic is the question, In what way are we to conceive logical objects, in particular, numbers? By what means are we justified in recognizing numbers as objects? Even if this problem is not solved to the degree I thought it was when I wrote this volume, still I do not doubt that the way to the solution has been found.
[from the Furth translation in Frege (1967)]

The Basic Problem for Frege's Strategy

The basic problem for Frege's strategy, however, is that for his logicist project to succeed, his system must at some point include (either as an axiom or theorem) statements that explicitly assert the existence of certain kinds of abstract entities and it is not obvious how to justify the claim that we know such explicit existential statements. Given our description of his system, it should be clear that Frege's logical system includes existence claims for the following entities:

- concepts
- extensions
- truth-values
- numbers

Although Frege attempted to reduce the latter two kinds of entities (truth-values and numbers) to extensions, the fact is that the existence of concepts and extensions are implied by his Rule of Substitution and Basic Law V, respectively. Logic, it is often argued, should be free of such existence assumptions. A Kantian might well complain both that explicit existence claims seem to be synthetic rather than analytic (i.e., such claims don't seem to be true in virtue of the meanings of the words involved) and that since the Rule of Substitution and Basic Law V imply existence claims, Frege cannot claim that such principles are purely analytic principles of logic. If so, then some other faculty (such as intuition) might still be needed to account for our knowledge of (the existence claims of) arithmetic.

The Existence of Concepts

Boolos (1985) was the first to note that the Rule of Substitution causes a problem of this kind for Frege's program, since it is equivalent to a quite liberal existential claim, namely, the Comprehension Principle for Concepts. Boolos suggests a defense for Frege with respect to this particular aspect of his logic, namely, to reinterpret (by paraphrasing) the second-order quantifiers so as to avoid commitment to concepts. (See Boolos (1985) for the details.) Boolos's suggestion, however, is one which would require Frege to abandon his realist theory of concepts. Moreover, although Boolos' suggestion might lead us to an epistemological justification of the Comprehension Principle for Concepts, it doesn't do the same for the Comprehension Principle for Relations, for his reinterpretation of the quantifiers works only for the ‘monadic’ quantifiers (i.e., those ranging over concepts having one argument) and thus doesn't offer a paraphrase for quantification over relational concepts.

Another problem for a strategy of the type suggested by Boolos is that if the second order quantifiers are interpreted so that they do not range over a separate domain of entities, then there is nothing appropriate to serve as the denotations of λ-expressions. Although Frege wouldn't quite put it this way, we have seen that his system treats open formulas with free object variables as if they denoted concepts. Although Frege doesn't use λ-notation, the use of such notation seems to be the most logically perspicuous way of reconstructing his work. The use of such notation faces the same epistemological puzzles that Frege's Rule of Substitution faces.

To see why, note that the Principle of λ-Conversion:

$$\forall y([\lambda x\, \varphi(x)]y \equiv \varphi(y/x))$$

seems to be an analytic truth of logic. It says this:

> An object *y* exemplifies the complex property *being an x such that* $\varphi(x)$ if and only if *y* satisfies (in Tarski's sense) φ

One might argue that this is true in virtue of the very meaning of the λ-expression, the meaning of $\equiv$, and the meaning of the statement form *Fx*. However, λ-Conversion also implies the Comprehension Principle for Concepts, for the latter follows from the former by existential generalization:

$$\exists F \forall y(Fy \equiv \varphi(y/x))$$

The point here is that the fact that an existential claim is derivable casts at least some doubt on the purely analytic status of λ-Conversion. The question of how we obtain knowledge of such principles is still an open question in philosophy. It is an important question to address, since Frege's most insightful definitions are cast using quantifiers ranging over concepts and relations (e.g., the ancestrals of a relation) and it would be useful to have a philosophical explanation of how such entities and the principles which govern them become known to us. In contemporary philosophy, this question is still poignant, since many philosophers do accept that *properties* and *relations* of various sorts exist. These entities are the contemporary analogues of Frege's concepts.

The Existence of Extensions

We have also seen (§2) that the Corollary to Basic Law V implies the existence of extensions. The question for Frege's project, then, is why should we accept as a law of logic a statement that implies the existence of individuals? Frege did conceive of Basic Law V as a law of logic:

> [**Gg I**, Preface, p. 3:]
> A dispute can arise, so far as I can see, only with regard to my Basic Law concerning courses-of-values (V)... I hold that it is a law of pure logic.
> [from the Furth translation in Frege (1967)]

Moreover, he thought that an appeal to extensions would answer one of the questions that motivated his work:

> [**Letter to Russell**, July 28, 1902:]
> I myself was long reluctant to recognize ranges of values and hence classes [sets]; but I saw no other possibility of placing arithmetic on a logical foundation. But the question is, How

> do we apprehend logical objects? And I have found no other answer to it than this, We apprehend them as extensions of concepts, or more generally, as ranges of values of functions.
>
> [from the Kaal translation in Frege (1980)]

Now it is unclear why Frege thought that he could answer the question posed here with the reply "We apprehend numbers as extensions of concepts". He seems to think we can answer the obvious next question "How do we apprehend extensions?" by saying "by way of Basic Law V". His idea here seems to be that since Basic Law V is supposed to be purely analytic or true in virtue of the meanings of its terms, we apprehend a pair of extensions whenever we truly judge that concepts *F* and *G* are materially equivalent. Some philosophers argue that Frege would have been correct to argue in just this way (had Basic Law V been consistent). They argue that Basic Law V (or consistent principles having the same logical form) justifies *reference* to the entities described in the left-side condition by grounding such reference in the *truth* of the right-side condition.[11]

But this, of course, raises an obvious problem. To justify reference to extensions, we must first justify the claim that those extensions exist. It is not clear that the claim that concepts are materially equivalent can justify such an existence claim. But given Frege's view that Basic Law V is analytic, it seems that he must hold that the right-side condition implies the corresponding left-side condition as a matter of meaning.[12]

This view, however, runs up against the following argument. Suppose the right hand condition implies the left-side condition as a matter of meaning. That is, suppose that (R) implies (L) as a matter of meaning:

(R) $\forall x(Fx \equiv Gx)$

(L) $\grave{\varepsilon}F\varepsilon = \grave{\alpha}G\alpha$

Now note that (L) itself can be analyzed, from a logical point of view. No matter whether we construe $\grave{\varepsilon}$ as an operator or a kind of definite description, (L) (i.e., "the extension of *F* = the extension of *G*") can be analyzed as the claim:

> There is an object *x* and an object *y* such that:
> (1) *x* is a unique extension of *F*,
> (2) *y* is a unique extension of *G*, and
> (3) *x* = *y*.

That is, for some defined or primitive notion *Extension*(*x*,*F*) (‘*x* is an extension of *F*’), (L) implies the analysis (D) as a matter of meaning:

(D) $\exists x\exists y[Extension(x,F)\ \&\ \forall z(Extension(z,F) \rightarrow z{=}x)\ \&$
$Extension(y,G)\ \&\ \forall z(Extension(z,G) \rightarrow z{=}y)\ \&$

$x = y$]

But if (R) implies (L) as a matter of meaning, and (L) implies (D) as a matter of meaning, then (R) implies (D) as a matter of meaning. This seems doubtful. The material equivalence of *F* and *G* does not imply the existence claim (D) as a matter of meaning, whatever notion of meaning is involved. [This argument attempts to show why Va (i.e., the right-to-left direction of Basic Law V) is not analytic. Below, it will be adapted to show that the right-to-left direction of Hume's Principle is not analytic. See Boolos (1997, 307 - 309), for reasons why Vb and the left-to-right direction of Hume's Principle are not analytic.]

The moral to be drawn here is that the modern Fregean must attempt to explain our knowledge of existence claims for abstract objects such as extensions head on, and not try to justify them indirectly, by attempting to justify claims that imply such existence claims. Even if we follow Frege in conceiving of extensions as ‘logical objects’, the question remains as to how the very claims that such objects exist can be true on logical or analytic grounds alone. We might agree that there must be logical objects of some sort if logic is to have a subject matter, but if Frege is to achieve his goal of showing that our knowledge of arithmetic is free of intuition, then the logical knowledge with which he identifies arithmetical knowledge must be either be *purely* analytic or shown otherwise to be free of intuition. We'll return to this theme in the final subsection.

The Existence of Numbers and Truth-Values: The Julius Caesar Problem

Given that the proof of Frege's Theorem makes no appeal to Basic Law V, some philosophers have argued Frege's best strategy for achieving his goal is to replace Basic Law V with Hume's Principle and argue that Hume's Principle is an analytic principle of logic.[13] However, we have just seen one reason why such a strategy does not suffice. The claim that Hume's Principle is an analytic principle of logic is subject to the same problem just posed for Basic Law V. The equinumerosity of *F* and *G* does not, as a matter of meaning, imply (identity claims that entail) the existence of numbers. When we analyze "$\#F = \#G$" in the same way that we analyzed "$\acute{\varepsilon}F\varepsilon = \acute{\alpha}G\alpha$" (i.e., by analyzing away the operator # or definite description "the number of *F*s" in terms of existence and uniqueness claims), it becomes clear that the equinumerosity of *F* and *G* does not, as a matter of meaning, imply the result of the analysis.

Moreover, Frege had his own reasons for not replacing Basic Law V with Hume's Principle. One reason was that he thought Hume's Principle offered no answer to the epistemological question, ‘How do we grasp or apprehend logical objects, such as the numbers?’. But Frege had another reason for not substituting Hume's Principle for Basic Law V, namely, that Hume's Principle would be subject to ‘the Julius Caesar problem’. Frege first raises this problem in connection with an inductive definition of ‘$n = \#F$’ that he tries out in **Gl**, §55. Concerning this definition, Frege says:

> [**Gl**, §55:]
> ... but we can never -- to take a crude example -- decide by means of our definitions whether any concept has the number Julius Caesar belonging to it, or whether that

conqueror of Gaul is a number or is not.

[from the Austin translation in Frege (1974)]

Frege raises this same concern again for a contextual definition that gives a ‘criterion of identity’ for the objects being defined. In **Gl** §66, Frege considers the following contextual definition of ‘the direction of line *x*’:

The direction of line *a* = the direction of line *b* if and only if *a* is parallel to *b*.

With regard to this definition, Frege says:

[**Gl**, §66:]

It will not, for instance, decide for us whether England is the same as the direction of the Earth's axis---if I may be forgiven an example which looks nonsensical. Naturally no one is going to confuse England with the direction of the Earth's axis; but that is no thanks to our definition of direction.

[from the Austin translation in Frege (1974)]

Now trouble for Hume's Principle begins to arise when we recognize that it is a contextual definition that has the same logical form as this definition for directions. It is central to Frege's view that the numbers are *objects*, and so he believes that it is incumbent upon him to say *which* objects they are. But the ‘Julius Caesar problem’ is that Hume's Principle, if considered as the sole principle offering identity conditions for numbers, doesn't describe the conditions under which an arbitrary object, say Julius Caesar, is or is not to be identified with the number of planets. That is, Hume's Principle doesn't define the condition ‘$\#F=x$’, for arbitrary *x*. It only offers identity conditions when *x* is an object we know to be a cardinal number (for then $x=\#G$, for some *G*, and Hume's Principle tells us when $\#F=\#G$).

In **Gl**, Frege solves the problem by giving his explicit definition of numbers in terms of extensions. (We described this in §4 above.) Unfortunately, this is only a stopgap measure, for when Frege later systematizes extensions in **Gg**, Basic Law V has the same logical form as Hume's Principle and the above contextual definition of directions. Frege is aware that the Julius Caesar problem affects Basic Law V, though. In **Gg I**, §10, Frege appears to raise the Julius Caesar problem for extensions of concepts. With respect to Basic Law V, he says:

[**Gg I**, §10:]

...this by no means fixes completely the denotation of a name like ‘$\grave{\varepsilon}\Phi(\varepsilon)$’. We have only a means of always recognizing a course-of-values if it is designated by a name like ‘$\grave{\varepsilon}\Phi(\varepsilon)$’, by which it is already recognizable as a course-of-values. But, we can neither decide, so far, whether an object is a course-of-values that is not given us as such ...

[from the Furth translation in Frege (1967)]

In other words, Basic Law V does not tell us the conditions under which an arbitrarily chosen object *x*

may be identified with some given extension, such as $\grave{\varepsilon} F\varepsilon$.

Until recently, it was thought that Frege solved this problem in §10 by restricting the universal quantifier $\forall x$ of his **Gg** system so that it ranges only over extensions. If Frege could have successfully restricted this quantifier to extensions, then when the question arises, is (arbitrarily chosen) object *x* is identical with $\grave{\varepsilon} F\varepsilon$, one could answer that *x* has to be the extension of some concept, say *G* and that Basic Law V would then tell you the conditions under which *x* is identical to $\grave{\varepsilon} F\varepsilon$. On this interpretation of §10, Frege is alleged to have restricted the quantifiers when he identified the two truth values (The True and The False) with the two extensions that contain just these objects as members, respectively. By doing this, it was thought that all of the objects in the range of his quantifier $\forall x$ in **Gg** become extensions which have been identified as such, for the truth values were the only two objects of his system that had not been introduced as extensions or courses of value.

However, recent work by Wehmeier (1999) suggests that, in §10, Frege was not attempting to restrict the quantifiers of his system to extensions (nor, more generally, to courses-of-values). The extensive footnote to §10 indicates that Frege considered, but did not hold much hope of, identifying every object in the domain with the extension consisting of just that object.[14] But, more importantly, Frege later considers cases (in **Gg**, Sections 34 and 35) which seem to presuppose that the domain contains objects which aren't extensions. (In these sections, Frege considers what happens to the definition of '*x* is a member of *y*' when *y* is not an extension.)[15]

Even if Frege somehow could have successfully restricted the quantifiers of **Gg** to avoid the Julius Caesar problem, he would no longer have been able to extend his system to include names of ordinary non-logical objects. For if he were to attempt to do so, the question, "Under what conditions is $\grave{\varepsilon} F\varepsilon$ identical with Julius Caesar?", would then be legitimate but have no answer. That means his logical system could not be used for the analysis of ordinary language. But it was just the analysis of ordinary language that led Frege to his insight that a statement of number is an assertion about a concept.

Final Observations

Even when we replace the inconsistent Basic Law V with the powerful Hume's Principle, Frege's work still leaves two questions unanswered: (1) How do we know that numbers exist?, and (2) How do we precisely specify which objects they are? The first question arises because Hume's Principle doesn't seem to be a purely analytic truth of logic; by what faculty do we come to know (the truth of) the existential claim that numbers exist if neither Hume's Principle nor this existential claim is analytically true? The second question arises because Frege's work offers no general condition under which we can identify an arbitrarily chosen object *x* with a given number such as the number of planets; how then can Frege claim to have precisely specified which objects the numbers are within the domain of all logical and non-logical objects? So questions about the very existence and identity of numbers still plague Frege's work.

These two questions arise because of a limitation in the logical form of these Fregean biconditional

principles such as Hume's Principle and Basic Law V. These contextual definitions attempt to do two jobs which modern logicians now typically accomplish with separate principles. A properly reformulated theory of ‘logical’ objects should have: (1) a separate *non-logical* comprehension principle which explicitly asserts the existence of *logical objects*, and (2) a separate identity principle which asserts the conditions under which *logical objects* are identical. The latter should specify identity conditions for logical objects in terms of their most salient characteristic, one which distinguishes them from other objects. Such an identity principle would then be more specific than the global identity principle for all objects (Leibniz's Law) which asserts that if objects x and y fall under the same concepts, they are identical.

By way of example, consider modern set theory. Zermelo set theory (Z) has a distinctive *non-logical* comprehension principle for sets:

> **Subset Axiom of Z**:
> $\forall x[Set(x) \rightarrow \exists y[Set(y) \,\&\, \forall z(z \in y \equiv z \in x \,\&\, \varphi(z))]]$,
> where $\varphi(z)$ is any formula in which the variable z is free and which has no free variables y

Z has a separate identity principle:

> **Identity Principle for Sets**:
> $Set(x) \,\&\, Set(y) \rightarrow [\forall z(z \in x \equiv z \in y) \rightarrow x = y]$

Note that the second principle offers identity conditions in terms of the most salient features of sets, namely, the fact that they, unlike other objects, have members. The identity conditions for objects which *aren't* sets, then, can be the standard principle that identifies objects whenever they fall under the same concepts. This leads us naturally to a very general principle of identity for any objects whatever:

> **General Principle of Identity**:
> $x = y \;\; =_{df} \;\; [Set(x) \,\&\, Set(y) \,\&\, \forall z(z \in x \equiv z \in y)] \;\; \vee$
> $\qquad\qquad [\neg Set(x) \,\&\, \neg Set(y) \,\&\, \forall F(Fx \equiv Fy)]$

Now, if something is given to us *as a set* and we ask whether it is identical with an arbitrarily chosen object x, this specifies a clear condition that settles the matter. The only questions that remain for the theory Z concern its existence principle: Do we know that the comprehension principle is true, and if so, how? The question of existence is thus laid bare. We do not approach it by attempting to justify a principle that implies the existence of sets via definite descriptions which we don't yet know to be well-defined.

In his classic essays (1987) and (1986), Boolos appears to recommend this very procedure of using separate existence and identity principles. In those essays, he eschews the primitive mathematical relation of set membership and suggests that Frege formulate his theory of numbers (‘Frege Arithmetic’) by using a single *nonlogical* comprehension axiom which employs a special instantiation relation that holds

between a concept G and an object x whenever, intuitively, x is an extension consisting solely of concepts and G is a concept ‘in’ x. He calls this nonlogical axiom ‘Numbers’ and uses the notation ‘$G\eta x$’ to signify that G is in x:

> **Numbers**:
> $\forall F \exists ! x \forall G(G \eta x \equiv G \approx F)$

[See Boolos (1987), p. 5; and (1986), p. 140.] This principle asserts that for any concept F, there is a unique object which contains in it all and only those concepts G which are equinumerous to F. Boolos then makes two observations: (1) that Frege can then define #F as "the unique object x such that for all concepts G, G is in x iff G is equinumerous to F", and (2) that Hume's Principle is derivable from Numbers. [See Boolos (1986), p. 140.] Given these observations, we know from our work in §§4 and 5 above that Numbers suffices for the derivation of the basic laws of arithmetic.

Since Boolos calls this principle ‘Numbers’, it is no stretch to suppose that he would accept the following explicit reformulation (in which ‘*Number*(x)’ is an undefined, primitive notion):

> **Numbers**:
> $\forall F \exists ! x[\mathit{Number}(x) \;\&\; \forall G(G \eta x \equiv G \approx F)]$

Though Boolos doesn't explicitly formulate an identity principle to complement Numbers, it seems clear that the following principle would offer identity conditions in terms of the most distinctive feature of numbers:

> **Identity Principle for Numbers**:
> $\mathit{Number}(x) \;\&\; \mathit{Number}(y) \rightarrow [\forall G(G \eta x \equiv G \eta y) \rightarrow x = y]$

It is then straightforward to formulate a general principle of identity, as we did in the case of the set theory Z:

> **General Principle of Identity**:
> $x = y \;=_{df}\; [\mathit{Number}(x) \;\&\; \mathit{Number}(y) \;\&\; \forall F(F \eta x \equiv F \eta y)] \;\lor$
> $[\neg \mathit{Number}(x) \;\&\; \neg \mathit{Number}(y) \;\&\; \forall F(Fx \equiv Fy)]$

This formulation of Frege Arithmetic, in terms of Numbers and the General Principle of Identity, puts the Julius Caesar problem (described above) into better perspective; the condition ‘#F=x’ is defined for arbitrary concepts F and objects x. It openly faces the epistemological questions head-on: Do we know that Numbers is true, and if so, how? This is where philosophers need to concentrate their energies. [For a reconstruction of Frege Arithmetic with a more general version of the special instantiation relation η, see Zalta (1999).]

By replacing Fregean biconditionals such as Hume's Principle with explicit existence and identity

principles, we reduce two problems to one and and isolate the real problem for Fregean foundations of arithmetic, namely, the problem of giving an epistemological justification of existence claims (e.g., Numbers) for abstract objects of a certain kind. For anything like Frege's program to succeed, it must at some point explicitly assert (as an axiom or theorem) the existence of (logical) objects of some kind. Those explicit existence claims should be the focus of attention, for they are the point at which logic and metaphysics dovetail. The theory of logical objects, if carried out without any mathematical primitives, should simply be acknowledged as a nonlogical metaphysical theory, not a piece of logic. A proper epistemology for such a theory should offer some epistemological justification of the explicit existence claims that serve as the basic axioms of the theory. That is the moral to be drawn from Frege's work.

Acknowledgements

I am indebted to William Demopoulos, whose short essay "Gottlob Frege" for the forthcoming Garland Encyclopedia motivated me to write the present entry. Demopoulos has kindly allowed me to quote certain passages from that essay in the footnotes to the present entry. I am also indebted to Roberto Torretti, who carefully read this piece and identified numerous infelicities, and to Xu Mingming, who noticed that Fact 7 about the Weak Ancestral (Section 4, subsection "The Weak Ancestral of *R*") was missing an important condition (namely, that *R* must be 1-1). Finally, I am indebted to Kai Wehmeier,

who reminded me that, strictly speaking, the result of replacing Basic Law V by Hume's Principle in Frege's system does not result in a subsystem of the original, since we have to replace the primitive notion "the course of values of the function *f*" with the primitive notion "the number of *F*s".

A More Complex Example

Example of an Inference Using the Definition of Membership

If given the premise that

$$1 + 2^2 = 5$$

one can prove that

$$1 \in \acute{\epsilon}(\epsilon + 2^2 = 5)$$

For it follows from our premise (by λ-Abstraction) that:

$$[\lambda z\, z + 2^2 = 5]1$$

Independently, by the logic of identity, we know:

$$\acute{\epsilon}([\lambda z\, z + 2^2 = 5]\epsilon) \;=\; \acute{\epsilon}([\lambda z\, z + 2^2 = 5]\epsilon)$$

So we may conjoin this fact and the result of λ-Abstraction to produce:

$$\acute{\epsilon}([\lambda z\, z + 2^2 = 5]\epsilon) = \acute{\epsilon}([\lambda z\, z + 2^2 = 5]\epsilon) \;\;\&\;\; [\lambda z\, z + 2^2 = 5]1$$

Then, by existential generalization on the concept $[\lambda z\, z + 2^2 = 5]$, it follows that:

$$\exists G[\acute{\epsilon}([\lambda z\, z + 2^2 = 5]\epsilon) = \acute{\epsilon}G\epsilon \;\;\&\;\; G1]$$

By the definition of membership, we obtain:

$$1 \in \acute{\epsilon}([\lambda z\, z + 2^2 = 5]\epsilon)$$

And, finally, by our Rewrite Rule, we establish what we set out to prove:

$1 \in \grave{\varepsilon}(\varepsilon + 2^2 = 5)$

Proof of the Law of Extensions

We want to show, for an arbitrarily chosen concept P and an arbitrarily chosen object c, that $c \in \grave{\varepsilon}P\varepsilon \equiv Pc$.

($\rightarrow$) Assume $c \in \grave{\varepsilon}P\varepsilon$ (to show Pc). Then, by the definition of $\in$, it follows that:

$$\exists H(\grave{\varepsilon}P\varepsilon = \grave{\alpha}H\alpha \;\&\; Hc)$$

Suppose that Q is such a property. Then, we know:

$$\grave{\varepsilon}P\varepsilon = \grave{\alpha}Q\alpha \;\&\; Qc$$

But, by Basic Law V, the first conjunct implies $\forall x(Px \equiv Qx)$. So from the fact that Qc, it follows that Pc.

($\leftarrow$) Assume Pc (to show $c \in \grave{\varepsilon}P\varepsilon$). Then, by the Corollary to Basic Law V, P has an extension, namely, $\grave{\varepsilon}P\varepsilon$. So by the laws of identity, we know $\grave{\varepsilon}P\varepsilon = \grave{\varepsilon}P\varepsilon$. We may conjoin this with our assumption to conclude:

$$\grave{\varepsilon}P\varepsilon = \grave{\varepsilon}P\varepsilon \;\&\; Pc$$

Now by existential generalizing on the concept P, it follows that:

$$\exists H(\grave{\varepsilon}P\varepsilon = \grave{\varepsilon}H\varepsilon \;\&\; Hc)$$

Thus, by the definition of $\in$, it follows that $c \in \grave{\varepsilon}P\varepsilon$.

Proof of the Principle of Extensionality from Basic Law V

Assume $Extension(x)$ and $Extension(y)$. Then $\exists F(x = \grave{\varepsilon} F\varepsilon)$ and $\exists F(y = \grave{\alpha} F\alpha)$. Let, P, Q be arbitrary such concepts; i.e., suppose $x = \grave{\varepsilon} P\varepsilon$ and $y = \grave{\alpha} Q\alpha$.

Now to complete the proof, assume $\forall z(z \in x \equiv z \in y)$. It then follows that $\forall z(z \in \grave{\varepsilon} P\varepsilon \equiv z \in \grave{\alpha} Q\alpha)$. So, by the Law of Extensions and the principles of predicate logic, we may convert both conditions in the universalized biconditional to establish that $\forall z(Pz \equiv Qz)$. So, by Basic Law V, $\grave{\varepsilon} P\varepsilon = \grave{\alpha} Q\alpha$. So $x = y$.

First Derivation of the Contradiction

The λ-expression which denotes the concept *being the extension of a concept which you don't fall under* is:

$$[\lambda x\, \exists F(x = \grave{\alpha} F\alpha \ \&\ \neg Fx)]$$

As we saw in the text, we know that such a concept as this exists, by the Comprehension Principle for Concepts. Let 'G' abbreviate this name of the concept. So $\grave{\varepsilon}G\varepsilon$ exists, by the Corollary to Basic Law V. Now suppose $\grave{\varepsilon}G\varepsilon$ falls under the concept G; i.e., suppose:

$$[\lambda x\, \exists F(x = \grave{\alpha} F\alpha \ \&\ \neg Fx)]\, \grave{\varepsilon}G\varepsilon$$

Then, by the principle of λ-conversion, it follows that:

$$\exists F(\grave{\varepsilon}G\varepsilon = \grave{\alpha}F\alpha \ \&\ \neg F\grave{\varepsilon}G\varepsilon)$$

Let H be an arbitrary such concept. So we know the following about H:

$$\grave{\varepsilon}G\varepsilon = \grave{\alpha}H\alpha \ \&\ \neg H\grave{\varepsilon}G\varepsilon$$

Now given Law V, it follows from the first conjunct that $\forall x(Gx \equiv Hx)$. So since $\grave{\varepsilon}G\varepsilon$ fails to fall under H, it fails to fall under G, contrary to hypothesis.

So then suppose $\grave{\varepsilon}G\varepsilon$ fails to fall under G. Then, again by λ-conversion, we know:

$$\neg\exists F(\grave{\varepsilon}G\varepsilon = \grave{\alpha}F\alpha \ \&\ \neg F\grave{\varepsilon}G\varepsilon),$$

i.e.,

$$\forall F(\grave{\varepsilon}G\varepsilon = \grave{\alpha}F\alpha \rightarrow F\grave{\varepsilon}G\varepsilon)$$

But by instantiating this universal claim to G, it follows from the self-identity of $\grave{\varepsilon}G\varepsilon$ that $\grave{\varepsilon}G\varepsilon$ does fall under the concept G, contrary to hypothesis. Contradiction.

Notes to Frege's Logic, Theorem, and Foundations for Arithmetic

---

Notes

1. These models of second-order logic with a Comprehension Principle for Concepts are called ‘general models’ (as opposed to ‘standard’ models in which the domain of concepts is taken to be the power set of domain of objects). These general models exploit the fact that there are only a denumerably infinite number of conditions on objects expressible in the language and hence, only a denumerably infinite number of instances of comprehension. These general models include in the domain of concepts only enough concepts to make these instances of comprehension true. Thus, only a denumerably infinite number of concepts are required, even if the domain of objects is denumerably infinite. So we emphasize that it is the interaction of the Comprehension Principle for Concepts with Vb that engenders the paradox.

2. It is important to note here that Frege's definitions of the membership relation and the notion of equinumerosity require a second-order language, since both definitions involve quantification over concepts.

3. Frege doesn't call this principle ‘Hume's Principle’ in his own writings. The label was instead introduced in Boolos (1987). Frege did cite Hume when he introduced this principle in **Gl**. In **Gl**, §63, he quotes Hume's *Treatise* (I, iii, 1):

> When two numbers are so combined as that one has always an unite answering to every unite of the other, we pronounce them equal.

The idea in Hume does bear some resemblance to the principle Frege constructs, and so we shall continue to use Boolos' label for this principle.

4. We call this an implicit or contextual definition rather than an explicit definition because the notation $\#F$ can only be eliminated when it appears in a context of the form ‘$\#F = \#G$’. By contrast, an explicit definition would take the form:

$$\#F \;\; =_{df} \;\; \text{the object } x \text{ such that } \wp(x,F),$$

where $\wp(x,F)$ is some condition on x and F. This would allow us to eliminate the $\#F$ no matter in which context it appears. We shall examine Frege's attempt to give such a definition momentarily.

The reader might also find the following observation by Demopoulos useful:

> Moreover, Frege's contextual definition (i.e., Hume's Principle) is not ‘conservative’ over the language L = {0, S, N} of second order arithmetic. (It is not conservative because it allows one to prove statements that are otherwise unprovable using this language and second-order logic alone. A proper, explicit definition only introduces simplifying notation --- the new theorems formulable with the new notation introduced by an explicit definition would still have been provable had the new notation been eliminated in terms of primitive notation. As such, explicit definitions are conservative.) Indeed, the contextual definition allows for the proof *both* of the infinity of the sequence of natural numbers *and* of the existence of an infinite cardinal (which Frege called ‘endlos’ in **Gl**).

[from Demopoulos (forthcoming-a)]

5. The reader might find the following observation by Demopoulos useful.

> The characterization "Frege-Russell", nearly universal and certainly well-established, actually slurs over the fact that, from the point of view of Russell's Simple Theory of Types, the number associated with a set (the analogue, in this setting, of a concept of first level) is an entity of higher type than the set itself. Beginning with individuals -- entities of lowest type -- Russell proceeds first to sets of individuals (corresponding to Frege's first-level concepts) and thence to classes of such sets (corresponding to Frege's concepts of second level). For Russell, since numbers are classes of equinumerous sets, they are of higher type than sets. But for Frege, extensions, and therefore numbers, belong to the totality of objects *whatever the level of concept with which they are associated*. Thus, while Russell and Frege both subscribe to *some* version of Hume's Principle, their conceptions of the logical form of the cardinality operator, and therefore, that of the principle itself, are quite different: the operator is "type-raising" for Russell, since it takes us from a set to a class; while for Frege it is "type-lowering", since it takes a concept (set) to an object (individual). This difference is fundamental, since it enables Frege to establish -- on the basis of Hume's principle -- those of the Peano-Dedekind axioms of arithmetic which assert that the system of natural numbers is, in Dedekind's phrase, "simply infinite" (Dedekind infinite). By contrast, when the cardinality operator is type raising, Hume's principle is rather weak, allowing for models of every finite power. (See Bell (1996) and Boolos (1994) for further discussion of these matters.)

[from Demopoulos (forthcoming-a)]

6. The higher-order version of the Law of Extensions asserts that a concept *G* is a member of the extension of the second-order concept *concept equinumerous to F* iff *G* is equinumerous to *F*. If we temporarily suppose that the variable ε can be used a variable ranging over concepts, then we could represent the extension of the second-order concept just described as:

$\grave{\varepsilon}(\varepsilon \approx F)$

Then, the higher-order law of extensions would be formalizable as follows:

$$G \in \grave{\varepsilon}(\varepsilon \approx F) \;\equiv\; G \approx F$$

This principle is used implicitly on several occasions in the derivation of Hume's Principle in **Gl**. Those readers who read the material on the derivation of Hume's Principle in **Gg** will see that this principle gets reformulated as the Lemma to the Proof of Hume's Principle.

7. Strictly speaking, we should represent this concept as follows:

$$[\lambda z\, [\lambda y\, Ayp]z \;\&\; z \neq r]$$

But we have applied the following instance of λ-Conversion to the first conjunct within the matrix of the λ-expression:

$$[\lambda y\, Ayp]z \equiv Azp$$

We thereby simplify the entire expression to:

$$[\lambda z\, Azp \;\&\; z \neq r]$$

8. The Facts numbered 3, 4, 5, and 6 correspond to Theorems 124, 129, 123, and 128, respectively, in **Gg I**. Facts 1, 6, and 7 correspond to Propositions 91, 84, and 98, respectively, in Part III of **Begr**.

9. Facts 2, 3, 5, and 6 correspond to Theorems 134, 132, 141, and 144, respectively, in **Gg I**.

10. A relation *R* is one-to-one ("*R* is 1-1") just in case it satisfies the following condition:

$$Rxz \;\&\; Ryz \rightarrow x=y$$

So Fact 7 in the text is a fact about the weak ancestral whenever the relation *R* in question is 1-1. We shall prove that the Predecessor relation is 1-1 in the third subsection of Section 5. Then Fact 7 and the fact that Predecessor is 1-1 will both play a crucial role in the proof that every number has a successor.

To prove Fact 7, assume that $R^*(a,b)$, *Rcb* and that *R* is 1-1. We want to show $R^+(a,c)$. Now by Fact 5 concerning the weak ancestral, we know that it follows from $R^*(a,b)$ that $\exists z[Rzb \;\&\; R^+(a,z)]$. So call an arbitrary such object "*d*". So we know $Rdb \;\&\; R^+(a,d)$. Now since R is 1-1, it follows from *Rdb* and *Rcb*,

that $c=d$. So, $R^+(a,c)$, which is what we had to show.

11. See the work by Wright cited in the Bibliography for a defense of something like this position. Wright justifies this position on Fregean grounds by appealing to Frege's Context Principle, which asserts that a word has no meaning (reference) except in the context of a proposition (truth).

12. See the paper by Rosen in the Bibliography for a full discussion of how someone might claim that the right-hand condition of an instance might imply its corresponding left-hand condition.

13. Again, see the work by Wright cited in the Bibliography.

14. In the long footnote to §10, Frege seems to suggest that the idea of replacing the truth values with their unit classes cannot be extended to the case of every object in the domain without conflicting with his earlier stipulations (in **Gg I**, §§3, 9 and 20), and in particular, with Basic Law V.

15. Wehmeier (1999) also shows that Frege could not have had much luck restricting the quantifiers of **Gg** to extensions. Wehmeier considers two consistent subsytems that Frege might have adopted to avoid the contradiction, namely, the system H described in Heck (1996) and the system Wehmeier himself describes and labels T△. Both of these systems retain Basic Law V but place restrictions on the Comprehension Principle for Concepts. However, Wehmeier shows that both systems imply the existence of objects which are not extensions (or courses-of-values), and indeed, they imply an infinite number of such objects.

Frege's Derivation of Hume's Principle in Gl

The Derivation of Hume's Principle in **Gl**, #73, appeals to the following principle, which is a higher-order version of the Law of Extensions:

> *Principle*: G is an member of the extension of the second-order concept *equinumerous to F* iff G is equinumerous to F

Now Hume's Principle is that the number of Fs is identical to the number of Gs iff F and G are equinumerous. We prove the biconditional in stages.

($\rightarrow$) Assume that the number of Ps is identical to the number of Qs. Then, by the definitions of 'the number of Ps' and 'the number of Qs', we know that the extension of the concept *equinumerous to P* is identical with the extension of the concept *equinumerous to Q*. But it is a fact about equinumerosity that P is equinumerous to P. So by the above Principle, the extension of the concept *equinumerous to P* has P as a member. So, by substitution of identicals, the extension of the concept *equinumerous to Q* has P as an member. So P is equinumerous to Q, by the above Principle.

($\leftarrow$) Assume P is equinumerous with Q. We want to show that the number of Ps is identical to the number of Qs. So, by definition, we have to show that the extension of the concept *equinumerous to P* is identical to the extension of the concept *equinumerous to Q*. By the Principle of Extensionality, then, we have to show that these two extensions have the same members! So we pick an arbitrary concept S and show that S is a member of the extension of the concept *equinumerous to P* iff S is a member of the extension of the concept *equinumerous to Q*.

> ($\rightarrow$) Assume S is a member of the extension of the concept *equinumerous to P* (to show: S is a member of the extension of the concept *equinumerous to Q*). Then, by the above Principle, S is equinumerous to P. So by the transitivity of equinumerosity (this is Fact 4 in the subsection on Equinumerosity in the main portion of the entry), S is equinumerous to Q. So, by the above Principle, S is in the extension of the concept *equinumerous to Q*
>
> ($\leftarrow$) Assume S is a member of the extension of the concept *equinumerous to Q* (to show: S is a member of the extension of the concept *equinumerous to P*). Then S is equinumerous to Q, by the above Principle. By the symmetry of equinumerosity (Fact 3 in the subsection on Equinumerosity), it follows that Q is equinumerous to S. So, given our hypothesis that P is

symmetry of equinumerosity (Fact 3 in the subsection on Equinumerosity), it follows that Q is equinumerous to S. So, given our hypothesis that P is equinumerous to Q, it follows by the transitivity of equinumerosity, that P is equinumerous to S. So, again by symmetry, we have: S is equinumerous to P. And, by the above Principle, it follows S is in the extension of the concept *equinumerous to* P.

Frege's ‘Derivation’ of Hume's Principle in Gg

In **Gg**, Fregean extensions do *not* contain concepts as members but rather objects. So Frege had to find another way to express the explicit definition of #*F*. His technique was to let extensions go proxy for their corresponding concepts. We may describe Frege's technique as follows. (What follows is an adaptation and simplification of the strategy Frege outlines in **Gg** I, §34ff.) Instead of defining the number of *F*s as the extension consisting of all those first-order concepts that are equinumerous to *F*, he defined it as the extension consisting of all the extensions of concepts equinumerous to *F*. Here is a formula which says: *x is an extension of a concept that is equinumerous to F*:

$$\exists H(x = \acute{\alpha} H\alpha \quad \& \quad H \approx F)$$

We can name this concept using our λ-notation as follows:

$$[\lambda x\, \exists H(x = \acute{\alpha} H\alpha \quad \& \quad H \approx F)]$$

Instead of writing out this lengthy expression *being an x which is an extension of a concept equinumerous to F*, let us abbreviate our λ-notation for this concept as ‘$F^{\#}$’. Note that the extension of this concept, $\acute{\varepsilon} F^{\#}(\varepsilon)$, contains only extensions as members.

Now Frege's explicit definition of ‘the number of *F*s’ can be given as follows:

$$\#F \quad =_{df} \quad \acute{\varepsilon} F^{\#}(\varepsilon)$$

This definition identifies the number of *F*s as the extension that contains all and only those extensions of concepts that are equinumerous to *F*.

We can complete our preliminary work for the proof of Hume's Principle by formulating and proving the following Lemma (derived from Basic Law V), which simplifies the proof of Hume's Principle:

Lemma for Hume's Principle:
$\acute{\varepsilon} G\varepsilon \in \#F \quad \equiv \quad G \approx F$

(Proof of the Lemma for Hume's Principle)

This Lemma tells us that an extension such as ἐGε will be a member of #*F* just in case *G* is equinumerous to *F*. Clearly, since *F* is equinumerous to itself, it follows that #*F* contains ἐFα as a member. From these facts, one can get a sense of how Frege derived Hume's Principle Basic Law V in **Gg**. Here is a reconstruction of the argument.

Proof of Hume's Principle from Basic Law V

Proof of the Lemma for Hume's Principle

Let P, Q be arbitrarily chosen concepts. We want to show:

$$\grave{\varepsilon}Q\varepsilon \in \#P \equiv Q \approx P$$

So, by definition of $\#F$, we have to show:

$$\grave{\varepsilon}Q\varepsilon \in \grave{\alpha}P^{\#}\alpha \equiv Q \approx P$$

We prove this by appealing to the Law of Extensions, which yields the following Fact:

$$Fact\text{: } \grave{\varepsilon}Q\varepsilon \in \grave{\alpha}P^{\#}\alpha \equiv P^{\#}(\grave{\varepsilon}Q\varepsilon)$$

($\rightarrow$) Assume $\grave{\varepsilon}Q\varepsilon \in \grave{\alpha}P^{\#}\alpha$ (to show: $Q \approx P$). Then, by the above Fact, we know $P^{\#}(\grave{\varepsilon}Q\varepsilon)$, i.e.,

$$[\lambda x\, \exists H(x = \grave{\alpha}H\alpha \;\&\; H \approx P)](\grave{\varepsilon}Q\varepsilon)$$

By λ-conversion, this implies:

$$\exists H(\grave{\varepsilon}Q\varepsilon = \grave{\alpha}H\alpha \;\&\; H \approx P)$$

Let R be such a concept:

$$\grave{\varepsilon}Q\varepsilon = \grave{\alpha}R\alpha \;\&\; R \approx P \tag{1}$$

But, by Basic Law V, the first conjunct implies $\forall x(Qx \equiv Rx)$. Since the material equivalence of two concepts implies their equinumerosity (this was noted as Fact 1 in the subsection on Equinumerosity in the main part of the entry), it follows that $Q \approx R$. So from this result and the second conjunct of (1), it follows that $Q \approx P$, by the transitivity of equinumerosity (Fact 4 in the subsection on Equinumerosity).

($\rightarrow$) Assume $Q \approx P$ (to show: $\grave{\varepsilon}Q\varepsilon \in \grave{\alpha}P^{\#}\alpha$). Then, by identity introduction, we know: $\grave{\varepsilon}Q\varepsilon = \grave{\varepsilon}Q\varepsilon \;\&\; Q \approx P$. So, by existential generalization:

$$\exists H(\grave{\varepsilon}Q\varepsilon = \grave{\alpha}H\alpha \;\&\; H \approx P)$$

$$\exists H(\grave{\varepsilon}Q\varepsilon = \grave{\alpha}H\alpha \;\&\; H \approx P)$$

And by λ-Conversion:

$$[\lambda x\, \exists H(x = \grave{\alpha}H\alpha \;\&\; H \approx P)](\grave{\varepsilon}Q\varepsilon)$$

So, by the Law of Extensions, $\grave{\varepsilon}Q\varepsilon \in \grave{\alpha}P\#\alpha$.

Proof of Hume's Principle from Basic Law V
Grundgesetze-Style

Let P, Q be arbitrarily chosen concepts. We want to show:

$$\#P = \#Q \equiv P \approx Q$$

($\rightarrow$) Assume $\#P = \#Q$ (to show: $P \approx Q$). Note that since $P \approx P$ (this is Fact 2 in the subsection on Equinumerosity), we know by the previous Lemma that $\grave{\varepsilon}P\varepsilon \in \#P$. But then, by identity substitution, $\grave{\varepsilon}P\varepsilon \in \#Q$. So, by our previous Lemma, $P \approx Q$.

($\leftarrow$) Assume $P \approx Q$ (to show: $\#P = \#Q$). By definition of $\#$, we have to show $\grave{\varepsilon}P^{\#}\varepsilon = \grave{\alpha}Q^{\#}\alpha$. So, by Basic Law V, we have to show $\forall x(P^{\#}x \equiv Q^{\#}x)$. Since pick an arbitrary object b (to show: $P^{\#}b \equiv Q^{\#}b$).

> ($\rightarrow$) Assume $P^{\#}b$. Then, by definition of $P^{\#}$ and λ-Conversion, $\exists H(b = \grave{\alpha}H\alpha \ \& \ H \approx P)$. Let R be an arbitrary such concept; so $b = \grave{\alpha}R\alpha \ \& \ R \approx P$. From the second conjunct and our initial hypothesis, it follows (by the transitivity of equinumerosity) that $R \approx Q$. So, reassembling what we know, it follows that $b = \grave{\alpha}R\alpha \ \& \ R \approx Q$. By existential generalization, it follows that $\exists H(b = \grave{\alpha}H\alpha \ \& \ H \approx Q)$. So by λ-Conversion,
>
> $$[\lambda x \ \exists H(b = \grave{\alpha}H\alpha \ \& \ H \approx Q)]b$$
>
> It follows from this, by definition, that $Q^{\#}b$.
>
> ($\leftarrow$) (Exercise)

Proof of Fact 5 Concerning the Weak Ancestral

Fact 5 concerning the weak ancestral R^+ of Rasserts:

> **Fact 5 (R^+)**:
> $R^*(x,y) \rightarrow \exists z[Rzy \mathbin{\&} R^+(x,z)]$

To prove this, we shall appeal to Fact 5 concerning the ancestral R^* of R:

> **Fact 5 (R^*)**:
> $[R^*(x,y) \mathbin{\&} \forall u(Rxu \rightarrow Fu) \mathbin{\&} \text{Her}(F,R)] \rightarrow Fy$,

for any concept F and objects x and y:

Now to prove Fact 5 (R^+), assume $R^*(a,b)$. We want to show:

> $\exists z[Rzb \mathbin{\&} R^+(a,z)]$

Notice that by λ-Conversion, it suffices to show:

> $[\lambda w\ \ \exists z[Rzw \mathbin{\&} R^+(a,z)]b$

Let us use 'P' to denote this concept under which (we have to show) b falls. Notice that we could prove Pb by instantiating Fact 5 (R^*) to P, a, and b and establishing the antecedent of the result. In other words, by Fact (R^*), we know:

> $[R^*(a,b) \mathbin{\&} \forall u(Rau \rightarrow Pu) \mathbin{\&} \text{Her}(P,R)] \rightarrow Pb$

So if we can show the conjuncts of the antecedent, we are done. The first conjunct is already established, by hypothesis. So we have to show:

> (1) $\forall u(Rau \rightarrow Pu)$
> (2) $\text{Her}(P,R)$

To see what we have to show for (1), we expand our defined notation and simplify by using λ-Conversion. Thus, we have to show:

(1) $\forall u[Rau \rightarrow \exists z(Rzu \,\&\, R^{+}(a,z))]$

So assume *Rau*, to show the consequent of (1). But it is an immediate consequence of the definition of the weak ancestral R^{+} that R^{+} is reflexive. (This is Fact 8 concerning the weak ancestral, in Section 4, "The Weak Ancestral of *R*".) So we may conjoin and conclude $Rau \,\&\, R^{+}(a,a)$. From this, we may infer consequent of (1), by existential generalization, which is what we had to show.

To show (2), we have to show that *P* is hereditary on *R*. If we expand our defined notation and simplify by using λ-Conversion), then we have to show:

(2) $Rxy \rightarrow [\exists z(Rzx \,\&\, R^{+}(a,z)) \rightarrow \exists z(Rzy \,\&\, R^{+}(a,z))]$

So assume

(A) $Rxy \,\&\, \exists z(Rzx \,\&\, R^{+}(a,z))$

to show: $\exists z(Rzy \,\&\, R^{+}(a,z))$. From the second conjunct of (A), we know that there is some object, say *d*, such that:

$Rdx \,\&\, R^{+}(a,d)$; i.e.,
$R^{+}(a,d) \,\&\, Rdx$

So, by Fact 2 about the weak ancestral (Section 4, "The Weak Ancestral of *R*"), it follows that $R^{*}(a,x)$, from which it immediately follows that $R^{+}(a,x)$, by definition of R^{+}. So, by appealing to the first conjunct of (A), we have:

$Rxy \,\&\, R^{+}(a,x)$,

from which it follows that:

$\exists z(Rzy \,\&\, R^{+}(a,z))$,

which is what we had to show.

Proof of Lemma Concerning Zero

Let P be an arbitrarily chosen concept. We want to show $\#P = 0 \equiv \neg\exists x Px$.

($\rightarrow$) Assume $\#P = 0$. Then, by definition of 0, $\#P = \#[\lambda z\, z \neq z]$. So by Hume's Principle, P is equinumerous to $[\lambda z\, z \neq z]$. So, by the definition of equinumerosity, there is an R that maps every object falling under P to a unique object falling under $[\lambda z\, z \neq z]$ and vice versa. Suppose, for reductio, that $\exists x Px$, say Pa. Then there is an object, say b, such that Rab and $[\lambda z\, z \neq z]b$. But, then, by λ-Conversion, b is not self-identical, which contradicts the laws of identity.

($\leftarrow$) Suppose $\neg\exists x Px$. Now as we have seen, the laws of identity guarantee that no object falls under the concept $[\lambda z\, z \neq z]$. But then any relation you please bears witness to the fact that P is equinumerous with $[\lambda z\, z \neq z]$. For let R be some arbitrary relation. Then (a) every object falling under P bears R to a unique object falling under $[\lambda z z \neq z]$ (since there are no objects falling under P), and (b) every object falling under $[\lambda z\, z \neq z]$ is such that there is a unique object falling under P that bears R to it (since there are no objects exemplifying $[\lambda z\, z \neq z]$). Since P is therefore equinumerous with $[\lambda z\, z \neq z]$, it follows by Hume's Principle, that $\#[\lambda z z \neq z] = \#P$. But, then, by definition, $0 = \#P$.

Proof of Equinumerosity Lemma

In this proof of the Equinumerosity Lemma, we utilize the following abbreviation:

$$x = \imath y\varphi(y) =_{abbr} \exists y[\varphi(y) \ \& \ \forall z(\varphi(z/y) \rightarrow z = y) \ \& \ x = y]$$

We may read this as follows:

> x is identical to *the* object y which satisfies the condition φ $=_{df}$ there exists a y such that: (a) y satisfies the condition φ, (b) everything which satisfies the condition φ is identical to y, and (c) x is identical to y

It will be seen how this abbreviation is employed to simplify the definition of new relations. Given this new notation, it is straightforward to show:

> Principle of Descriptions: $x = \imath y\varphi(y) \rightarrow \varphi(x/y)$

In other words, if x is *the* object y that satisfies the condition $\varphi(y)$, then x satisfies the condition φ. (The proof is a simple exercise.) The appeal to this principle will be obvious in what follows.

Proof of Equinumerosity Lemma. Assume that $P \approx Q$, Pa, and Qb. So there is a relation, say R, such that (a) R maps every object falling under P to a unique object falling under Q and (b) for every object falling under Q there is a unique object falling under P which is R-related to it. Now we use P^{-a} to designate $[\lambda z\, Pz \,\&\, z \neq a]$, and we use Q^{-b} to designate $[\lambda z\, Qz \,\&\, z \neq b]$. We want to show that $P^{-a} \approx Q^{-b}$. By the definition of equinumerosity, we have to show that there is a relation R' which is a one-to-one function from the objects falling under P^{-a} onto the objects falling under Q^{-b}. We prove this by cases.

Case 1: Suppose Rab. Then we choose R' to be R itself. Clearly, R is then a one-to-one function from the objects of P^{-a} to the objects of Q^{-b}. But the proof can be given as follows. We show: (A) that R is a function from the objects of P^{-a} to the objects of Q^{-b}, and then (B) that R is a one-to-one function from the objects of P^{-a} onto the objects of Q^{-b}.

(A) Pick an arbitrary object, say c, such that $P^{-a}c$. We want to show that there is a unique object which falls under Q^{-b} and to which c bears R. Since $P^{-a}c$, we know that $Pc \ \& \ c \neq a$, by the definition of P^{-a}. But if Pc, then by our hypothesis that R is a witness to the equinumerosity of P and

then by our hypothesis that R is a witness to the equinumerosity of P and

Proof (cont'd)

Return to Main Text

Q, it follows that there is a unique object, say d, such that Qd and Rcd. But we are considering the case in which Rab and so from the established facts that Rcd and $c \neq a$, it follows by the one-to-one character of R that $b \neq d$. So we have that Qd and $d \neq b$, which establishes that $Q^{-b}d$. And we have also established that Rcd. So it remains to show that every other object that falls under Q^{-b} to which c bears R just is identical to d. So suppose $Q^{-b}e$ and Rce. Then by definition of Q^{-b}, it follows that Qe. But now $e = d$, for d is the unique object falling under Q to which c bears R. So there is a unique object which falls under Q^{-b} and to which c bears R.

(B) Pick an arbitrary object, say d, such that $Q^{-b}d$. We want to show that there is a unique object falling under P^{-a} that bears R to d. Since $Q^{-b}d$, we know Qd and $d \neq b$. From Qd and the fact that R witnesses the equinumerosity of P and Q, we know that there is a unique object, say c, that falls under P and which bears R to d. Since we are considering the case in which Rab, and we've established Rcd and $d \neq b$, it follows that $a \neq c$, by the functionality of R. Since we now have Pc and $c \neq a$, we have established that c falls under P^{-a}, and moreover, that Rcd. So it remains to prove that any other object that falls under P^{-a} and which bears R to d just is (identical to) c. But if f, say, falls under P^{-a} and bears R to d, then Pf, by definition of P^{-a}. But recall that c is the unique object falling under P which bears R to d. So $f = c$.

Case 2: Suppose $\neg Rab$. Then we choose R' to be the relation:

$$[\lambda xy\,(x \neq a \;\&\; y \neq b \;\&\; Rxy) \vee (x = \imath u(Pu \;\&\; Rub) \;\&\; y = \imath u(Qu \;\&\; Rau))]$$

To see that there is such a relation, note that once we replace the abbreviations $x = \imath u(Pu \;\&\; Rub)$ and $y = \imath u(Qu \;\&\; Rau)$ by primitive notation, the matrix of the λ-expression is a formula of the form $\varphi(x,y)$ which can be used in an instance of the Comprehension Principle for Relations.

Now we want to show that R' is a one-to-one function from the objects of P^{-a} onto the objects of Q^{-b}. We show (A) that R' is a function from the objects of P^{-a} to the objects of Q^{-b}, and then (B) that R' is a one-to-one function from the objects of P^{-a} onto the objects of Q^{-b}.

(A) To show that R' is a function from the objects of P^{-a} to the objects of Q^{-b}, pick an arbitrary object, say c, such that $P^{-a}c$. Then by definition of P^{-a}, we know that Pc and $c \neq a$. We need to find an object, say d for which the following three things hold: (i) $Q^{-b}d$, (ii) $R'cd$, and (iii) $\forall w(Q^{-b}w \;\&\; R'cw \rightarrow w = d)$. We find such a d in each of the following, mutually exclusive cases:

cases:

Proof (cont'd)

Return to Main Text

Case 1: Rcb. So, since we know that each object falling under Q is such that there is a unique object falling under P that is R-related to it, we know that $c = \imath u(Pu \,\&\, Rub)$. Then, since we know R maps a to a unique object falling under Q, we let d be that object. That is, d satisfies the defined condition $d = \imath u(Qu \,\&\, Rau)$. So Qd, Rad, and $\forall w(Qw \,\&\, Raw \rightarrow w = d)$. We now show that (i), (ii) and (iii) hold for d:

i) Since we know Qd, all we have to do to establish $Q^{-b}d$ is to show $d \neq b$. But we know Rad and we are considering the case where $\neg Rab$. So, by the laws of identity, $d \neq b$.

ii) To show $R'cd$, we need to establish:

$$(c \neq a \,\&\, d \neq b \,\&\, Rcd) \vee (c = \imath u(Pu \,\&\, Rub) \,\&\, d = \imath u(Qu \,\&\, Rau))$$

But the conjunctions of the right disjunct are true (by assumption and by choice, respectively). So $R'cd$.

iii) Suppose $Q^{-b}e$ (i.e., Qe and $e \neq b$) and $R'ce$. We want to show: $e = d$. Since $R'ce$, then:

$$(c \neq a \,\&\, e \neq b \,\&\, Rce) \vee (c = \imath u(Pu \,\&\, Rub) \,\&\, e = \imath u(Qu \,\&\, Rau))$$

But the left disjunct is impossible (we're considering the case where Rcb, yet the left disjunct asserts Rce and $e \neq b$, which together contradict the functionality of R). So the right disjunct must be true, in which case it follows from the fact that $e = \imath u(Qu \,\&\, Rau)$ that $e = d$, by the definition of d.

Case 2: $\neg Rcb$. We are under the assumption $P^{-a}c$ (i.e., Pc and $c \neq a$), and so we know by the definition of R and the fact that Pc that there is a unique object which falls under Q and to which c bears R. Choose d to be this object. So Qd, Rcd, and $\forall w(Qw \,\&\, Rcw \rightarrow w = d)$. We can now show that (i), (ii) and (iii) hold for d:

i) Since we know Qd, all we have to do to establish that $Q^{-b}d$ is to show $d \neq b$. We know that Rcd and we are considering the case where $\neg Rcb$. So it follows that $d \neq b$, by the laws of identity. So $Q^{-b}d$.

ii) To show $R'cd$, we need to establish:

$$(c \neq a \,\&\, d \neq b \,\&\, Rcd) \vee (c = \imath u(Pu \,\&\, Rub) \,\&\, d = \imath u(Qu \,\&\, Rau))$$

$$(c \neq a \ \& \ d \neq b \ \& \ Rcd) \vee (c = \iota u(Pu \ \& \ Rub) \ \& \ d = \iota u(Qu \ \& \ Rau))$$

[Proof (cont'd)]

[Return to Main Text]

But the conjuncts of the left disjunct are true, for $c \neq a$ (by assumption), $d \neq b$ (we just proved this), and Rcd (by the definition of d). So $R'cd$.

iii) Suppose $Q^{-b}e$ (i.e., Qe and $e \neq b$) and $R'ce$. We want to show: $e = d$. Since $R'ce$, then:

$$(c \neq a \;\&\; e \neq b \;\&\; Rce) \vee (c = \imath u(Pu \;\&\; Rub) \;\&\; e = \imath u(Qu \;\&\; Rau))$$

But the right disjunct is impossible (we're considering the case where $\neg Rcb$, yet the right disjunct asserts $c = \imath u(Pu \& Rub)$, which implies Rcb, a contradiction). So $c \neq a \;\& e \neq b \;\& Rce$. Since we now know that Qe and Rce, we know that $e = d$, since d is, by definition, the unique object falling under Q to which c bears R.

(B) To show that R' is a one-to-one function from the objects of P^{-a} onto the objects of Q^{-b}, pick an arbitrary object, say d, such that $Q^{-b}d$. Then by definition of Q^{-b}, we know that Qd and $d \neq b$. We need to find an object, say c, for which the following three things hold: (i) $P^{-a}c$, (ii) $R'cd$, and (iii) $\forall w(P^{-a}w \;\& R'wd \rightarrow w = c)$. We find such a c in each of the following, mutually exclusive cases:

Case 1: Rad. So $d = \imath u(Qu \;\&\; Rau)$. Then choose $c = \imath u(Pu \;\&\; Rub)$ (we know there is such an object). So Pc, Rcb, and $\forall w(Pw \& Rwb \rightarrow w = c)$. We now show that (i), (ii) and (iii) hold for c:

i) Since we know Pc, all we have to do to establish $P^{-a}c$ is to show $c \neq a$. But we know Rcb, and we are considering the case where $\neg Rab$. So, by the laws of identity, it follows that $c \neq a$.

ii) To show $R'cd$, we need to establish:

$$(c \neq a \;\&\; d \neq b \;\&\; Rcd) \vee (c = \imath u(Pu \;\&\; Rub) \;\&\; d = \imath u(Qu \;\&\; Rau))$$

But the conjuncts of the right disjunct are true (by choice and by assumption, respectively). So $R'cd$.

iii) Suppose $P^{-a}f$ (i.e., Pf and $f \neq a$) and $R'fd$. We want to show: $f = c$. Since $R'fd$, then:

$$(f \neq a \;\&\; d \neq b \;\&\; Rfd) \vee (f = \imath u(Pu \;\&\; Rub) \;\&\; d = \imath u(Qu \;\&\; Rau))$$

But the left disjunct is impossible (we're considering the case where Rad, yet the left disjunct asserts Rfd and $f \neq a$, which

where Rad, yet the left disjunct asserts Rfd and $f \neq a$, which

Proof (cont'd)

Return to Main Text

together contradict the fact that R is one-to-one). So the right disjunct must be true, in which case it follows from the fact that $f = \iota u(Pu \,\&\, Rub)$ that $f = c$, by the definition of c.

Case 2: $\neg Rad$. We are under the assumption $Q^{-b}d$ (i.e., Qd and $d \neq b$), and so we know by the definition of R and the fact that Qd that there is a unique object which falls under P and which bears R to d. Choose c to be this object. So Pc, Rcd, and $\forall w(Pw \,\&\, Rwd \rightarrow w = c)$. We can now show that (i), (ii), and (iii) hold for c:

i) Since we know Pc, all we have to do to establish that $P^{-a}c$ is to show $c \neq a$. But we know that Rcd, and we are considering the case in which $\neg Rad$. So it follows that $c \neq a$, by the laws of identity. So $P^{-a}c$.

ii) To show $R'cd$, we need to establish:

$$(c \neq a \,\&\, d \neq b \,\&\, Rcd) \vee (c = \iota u(Pu \,\&\, Rub) \,\&\, d = \iota u(Qu \,\&\, Rau))$$

But the conjuncts of the left disjunct are true, for $c \neq a$ (we just proved this), $d \neq b$ (by assumption), and Rcd (by the definition of c). So $R'cd$.

iii) Suppose $P^{-a}f$ (i.e., Pf and $f \neq a$) and $R'fd$. We want to show: $f = c$. Since $R'fd$, then:

$$(f \neq a \,\&\, d \neq b \,\&\, Rfd) \vee (f = \iota u(Pu \,\&\, Rub) \,\&\, d = \iota u(Qu \,\&\, Rau))$$

But the right disjunct is impossible (we're considering the case where $\neg Rad$, yet the right disjunct asserts $d = \iota u(Qu \,\&\, Rau)$, which implies Rad, a contradiction). So $f \neq a \,\&\, d \neq b \,\&\, Rfd$. Since we now know that Pf and Rfd, we know that $f = c$, since c is, by definition, the unique object falling under P which bears R to d. $\bowtie$

Proof of the General Principle of Induction

Assume the antecedent of the principle, eliminating the defined notation for $HerOn(F, {}^{a}R^{+})$:

$$Pa \;\&\; \forall x,y(R^{+}(a,x) \;\&\; R^{+}(a,y) \;\&\; Rxy \rightarrow (Px \rightarrow Py)).$$

We want to show, for an arbitrary object b, that if $R^{+}(a,b)$ then Pb. So assume $R^{+}(a,b)$. To show Pb, we appeal to Fact (6) about R^{+} (in our subsection on the Weak Ancestral in §4):

$$Fx \;\&\; R^{+}(x,y) \;\&\; Hereditary(F,R) \rightarrow Fy$$

Instantiate the variable F in this Fact to the property $[\lambda z\, R^{+}(a,z) \;\&\; Pz]$ (that there is such a property is guaranteed by the Comprehension Principle for Relations), and instantiate the variables x and y to the objects a and b, respectively. The result (after applying λ-Conversion) is therefore something that we have established as true :

$$R^{+}(a,a) \;\&\; Pa \;\&\; R^{+}(a,b) \;\&\; Hereditary([\lambda z\, R^{+}(a,z) \;\&\; Pz], R) \rightarrow R^{+}(a,b) \;\&\; Pb$$

So if we can establish the antecedent of this fact, we establish Pb. But we know that the first conjunct is true, by the definition of R^{+}. We know the second conjunct is true, by assumption. We know that the third conjunct is true, by further assumption. So if we can establish:

$$Hereditary([\lambda z\, R^{+}(a,z) \;\&\; Pz], R),$$

we are done. But, by the definition of heredity, this just means:

$$\forall x,y[Rxy \rightarrow ((R^{+}(a,x) \;\&\; Px) \rightarrow (R^{+}(a,y) \;\&\; Py)].$$

To prove this claim, we assume Rxy, $R^{+}(a,x)$, and Px (to show: $R^{+}(a,y)$ & Py). But from the facts that $R^{+}(a,x)$ and Rxy, it follows from Fact (2) about R^{+} (in our subsection on the Weak Ancestral) that $R^{*}(a,y)$. This implies $R^{+}(a,y)$, by the definition of R^{+}. But since we now have $R^{+}(a,x)$, $R^{+}(a,y)$, Rxy, and Px, it follows from the first assumption in the proof that

implies $R^+(a, y)$, by the definition of R^+. But since we now have $R^+(a, x)$, $R^+(a, y)$, Rxy, and Px, it follows from the first assumption in the proof that Py. ⋈

Proof that 0 Falls Under *Q*

The proof that 0 falls under *Q* is relatively straightforward. We want to show:

$[\lambda y\, Precedes(y,\#[\lambda z\, Precedes^{+}(z,y)])]0$

By λ-Conversion, it suffices to show:

$Precedes(0, \#[\lambda z\, Precedes^{+}(z,0)])$

So, by the definition of Predecessor, we have to show that there is a concept *F* and object *x* such that:

(1) Fx
(2) $\#[\lambda z\, Precedes^{+}(z,0)] = \#F$
(3) $0 = \#[\lambda u\, Fu \,\&\, u \neq x]$

We can demonstrate that there is an *F* and *x* for which (1), (2) and (3) hold if we pick *F* to be $[\lambda z\, Precedes^{+}(z,0)]$ and pick *x* to be 0. We now establish (1), (2), and (3) for these choices.

To show that (1) holds, we have to show:

$[\lambda z\, Precedes^{+}(z,0)]0$

But we know, from the definition of $Precedes^{+}$, that $Precedes^{+}(0,0)$, So by abstraction using λ-Conversion, we are done.

To show that (2) holds, we need do no work, since our choice of *F* requires us to show:

$\#[\lambda z\, Precedes^{+}(z,0)] = \#[\lambda z\, Precedes^{+}(z,0)]$,

which we know by the logic of identity.

To show (3) holds, we need to show:

(A) $0 = \#[\lambda u\ Precedes^{+}(u,0)\ \&\ u \neq 0]$

[Note that the λ-expression in (A) has been simplified by applying λ-Conversion to the following (which, strictly speaking, is what results when you substitute our choice for *F* in (3)):

$$[\lambda u\ [\lambda z\ Precedes^{+}(z,0)]u\ \&\ u \neq 0]$$

In what follows, we use the simplified version of this λ-expression.]

To show (A), it suffices to show the following, in virtue of the Lemma Concerning Zero (in our subsection on The Concept *Natural Number* in §4):

$$\neg\exists x\ ([\lambda u\ Precedes^{+}(u,0)\ \&\ u \neq 0]x)$$

And by λ-Conversion, it suffices to show:

(B) $\neg\exists x\ (Precedes^{+}(x,0)\ \&\ x \neq 0)$

We establish (B) as follows.

When we established Theorem 2 (i.e., the fact that 0 is not the successor of any number), we proved that nothing precedes 0:

$$\neg\exists x\ Precedes(x,0)$$

From this, and Fact (3) about R^* (in the subsection on the Ancestral of *R*, in §4), it follows that nothing ancestrally precedes 0:

$$\neg\exists x\ Precedes^{*}(x,0)$$

Now suppose (for *reductio*) the negation of (B); i.e, that there is some object, say *a*, such that $Precedes^{+}(a,0)$ and $a \neq 0$. Then, by definition of $Precedes^{+}$, it follows that either $Precedes^{*}(a,0)$ or $a = 0$. But since our reductio hypthesis includes that $a \neq 0$, it must be that $Precedes^{*}(a,0)$, which contradicts the fact displayed immediately above.

Proof that Q is Hereditary on the Natural Numbers

We want to prove the following claim:

> $HerOn(Q,\mathbb{N})$

The proof of this claim appeals to the following Lemma (cf. **Gg** I, Theorem 149):

> **Lemma on *Predecessor*$^+$:**
> $\mathbb{N}x \;\&\; Precedes(y,x) \rightarrow$
> $\#[\lambda z\, Precedes^+(z,y)] = \#[\lambda z\, Precedes^+(z,x) \;\&\; z \neq x]$
>
> (Proof of the Lemma on *Predecessor*$^+$)

Intuitively, the Lemma on Predecessor$^+$ tells us that if y precedes a number x, then $\#[\lambda z\, z \leq y]$ is identical to $\#[\lambda z\, z \leq x \;\&\; z \neq x]$.

Now to show $HerOn(Q,\mathbb{N})$, we have to show:

> $\forall n \forall m[Precedes(n,m) \rightarrow (Qn \rightarrow Qm)]$

If we replace 'Q' with its definition and simplify the result by λ-Conversion, then what we have to show is:

> $\forall n \forall m(Precedes(n,m) \rightarrow$
> $Precedes(n,\#[\lambda z\, Precedes^+(z,n)]) \rightarrow Precedes(m,\#[\lambda z\, Precedes^+(z,m)])$

(Intuitively, we have to show that if n precedes m, then if n precedes the number of numbers less than or equal to n, then m precedes the number of numbers less than or equal to m.) So, letting n and m be arbitrary, we assume both:

> (A) $Precedes(n,m)$
> (B) $Precedes(n,\#[\lambda z\, Precedes^+(z,n)])$

to show:

$Precedes(m,\#[\lambda z\ Precedes^{+}(z,m)])$

By the definition of Predecessor, we have to show that there is a concept *F* and object *x* such that:

(1) Fx
(2) $\#[\lambda z\ Precedes^{+}(z,m)] = \#F$
(3) $m = \#[\lambda u\ Fu \ \&\ u \neq x]$

We can demonstrate that there is an *F* and *x* for which (1), (2) and (3) hold if we pick *F* to be $[\lambda z\ Precedes^{+}(z,m)]$ and pick *x* to be *m*. We now establish (1), (2), and (3) for these choices.

To show that (1) holds, we have to show:

$[\lambda z\ Precedes^{+}(z,m)]m$

But we know, from the definition of $Precedes^{+}$, that $Precedes^{+}(m,m)$. So by abstraction using λ-Conversion, we are done.

To show that (2) holds, we need do no work, since our choice of *F* requires us to show:

$\#[\lambda z\ Precedes^{+}(z,m)] = \#[\lambda z\ Precedes^{+}(z,m)]$,

which we know by the logic of identity.

To show (3) holds, we need to show:

(C) $m = \#[\lambda u\ Precedes^{+}(u,m) \ \&\ u \neq m]$

[Note that the λ-expression in the above has been simplified by applying λ-Conversion to the following (which, strictly speaking, is what results when you substitute our choice for *F* in (3)):

$[\lambda u\ [\lambda z\ Precedes^{+}(z,m)]u \ \&\ u \neq m]$

In what follows, we use the simplified version of this λ-expression.]

Now in virtue of (A), (B) and the functionality of Predecessor (the proof of which was left as an exercise in the subsection No Two Numbers Have the Same Successor in §5), we know $m = \#[\lambda z\ Precedes^{+}(z,n)]$. So, substituting for *m* in (C), we have to show:

$\#[\lambda z\, Precedes^{+}(z,n)] = \#[\lambda u\, Precedes^{+}(u,m) \,\&\, u \neq m]$

But we can demonstrate this by appealing to the Lemma on Predecessor^{+} mentioned at the outset. We may instantiate the variables *x* and *y* in this Lemma to *m* and *n*, respectively, yielding:

$$\mathbb{N}m \,\&\, Precedes(n,m) \rightarrow \\ \#[\lambda z\, Precedes^{+}(z,n)] = \#[\lambda z\, Precedes^{+}(z,m) \,\&\, z \neq m]$$

Since the consequence is what we had to show, we are done, for the conjuncts of the antecedent are things we assumed to be true at the beginning of our conditional proof.

Proof of the Lemma on Predecessor$^+$

We wish to prove the Lemma on Predecessor$^+$, which asserts:

> **Lemma on *Predecessor*$^+$:**
> $\mathbb{N}x \,\&\, Precedes(y,x) \rightarrow$
> $\#[\lambda z\, Precedes^+(z,y)] = \#[\lambda z\, Precedes^+(z,x) \,\&\, z \neq x]$

Now this Lemma can be proved with the help of the following Lemma:

> **Lemma: No Number Ancestrally Precedes Itself**
> $\forall x[\mathbb{N}x \rightarrow \neg Precedes^*(x,x)]$
>
> (Proof) [Exercise for the Reader]

Now to prove the Lemma on Predecessor$^+$, assume that $\mathbb{N}n$ and $Precedes(m,n)$. We want to show:

$$\#[\lambda z\, Precedes^+(z,m)] = \#[\lambda z\, Precedes^+(z,n) \,\&\, z \neq n]$$

By Hume's Principle, it suffices to show:

$$[\lambda z\, Precedes^+(z,m)] \approx [\lambda z\, Precedes^+(z,n) \,\&\, z \neq n]$$

Now it is a fact about equinumerosity (see the Facts About Equinumerosity, in §3, Equinumerosity, Fact 1) that if two concepts are materially equivalent, then they are equinumerous. It therefore suffices to show that

$$\forall x([\lambda z\, Precedes^+(z,m)]x \equiv [\lambda z\, Precedes^+(z,n) \,\&\, z \neq n]x)$$

And by λ-Conversion, it suffices to show:

$$\forall x[Precedes^+(x,m) \equiv Precedes^+(x,n) \,\&\, x \neq n]$$

So let us pick an arbitrary object, say *a*, and show:

$Precedes^{+}(a,m) \equiv Precedes^{+}(a,n)\ \&\ a \neq n$

($\rightarrow$) Assume $Precedes^{+}(a,m)$. Then from our assumption that $Precedes(m,n)$ and a Fact about R^{+} (see §4, Weak Ancestral, Facts About R^{+}, Fact 2), it follows that $Precedes^{*}(a,n)$. *A fortiori*, then, $Precedes^{+}(a,n)$. Now by the Lemma mentioned at the outset of this proof, namely, No Natural Number Ancestrally Precedes Itself, we know that $\neg Precedes^{*}(n,n)$. Since *a* ancestrally precedes *n* and *n* does not, it follows that $a \neq n$. We have therefore proved what we were after, namely:

$Precedes^{+}(a,n)\ \&\ a \neq n$

($\leftarrow$) Assume $Precedes^{+}(a,n)$ and $a \neq n$. By definition, the first conjunct tells us that either $Precedes^{*}(a,n)$ or $a = n$. Since we know by assumption that the latter disjunct is not true, we know $Precedes^{*}(a,n)$. But from this fact, the fact that Predecessor is 1-1, and our assumption that $Precedes(m,n)$, it follows from a fact about R^{+} (see §4, Weak Ancestral, Facts About R^{+}, Fact 7), that $Precedes^{+}(a,m)$, which is what we had to show.

Semantic Challenges to Realism

According to realism, the world is as it is independently of how humans take it to be. The objects the world contains, together with their properties and the relations they enter into, fix the world's nature and these objects exist independently of our ability to discover they do. Unless this is so, realists argue, none of our beliefs about our world could be objectively true since true beliefs tell us how things are and beliefs are objective when true or false independently of what anyone might think. The issue of objectivity affects all of us deeply -- when we think the State has an obligation to provide adequate health care to all its citizens we mean to be describing what the State's obligations really are, independently of what anyone might think about the matter. If someone disagrees with us over this matter, we think they've got it wrong -- are mistaken about how things are as regards the State and its obligations. If there can be no objectivity without a mind-independent world, as realists claim, then there had better be a mind-independent world.

Many philosophers believe realism is just plain common sense. Others believe it to be a direct implication of modern science which paints humans as fallible creatures adrift in an inhospitable world not of their making. Nonetheless, realism is controversial. There are epistemological problems connected with it -- how can we obtain knowledge of a mind-independent world? There are also prior semantic problems -- how are the links between our beliefs and the mind-independent states of affairs they allegedly represent set up? This is the Representation Problem.

Anti-realists deny the world is mind-independent. Believing the Representation Problem to be insoluble for realists, they conclude realism must be false. In this article I review a number of anti-realist semantic challenges to realism all based on the Representation Problem: (i) The Manifestation Challenge claims the cognitive and linguistic behaviour of an agent provides no evidence that realist mind/world links exist. (ii) The Language Acquisition Challenge claims that if such links were to exist language learning would be impossible. (iii) The Brain in a Vat Challenge holds that realism entails both that we could be massively deluded ("Brains in a Vat") and that if we were we could not even form the belief that we were. (iv) The Conceptual Relativity Challenge alleges it is senseless to ask what the world contains independently of how we conceive of it. The objects that exist depend on the conceptual scheme used to classify them. (v) The Model-Theoretic Challenge contends realist must either hold that an ideal theory passing every conceivable test could be false or that perfectly determinate terms like ‘cat’ are massively indeterminate. Both alternatives are absurd according to anti-realists.

I proceed by first defining realism, illustrating its distinctive mind-independence claim with some examples and distinguishing it from a doctrine with which it is often confused, factualism. I then outline the Representation Problem, saying why it is a problem for realism before presenting the anti-realist's

semantic challenges to realism which are all based on it. I discuss realist responses to these challenges, indicating how the debates have proceeded, suggesting various alternatives on the way and countenancing anti-realist replies. I finish with my own evaluation of the problems facing realists and anti-realists and prospects for resolution.

---

1. What is Realism

Realism is the thesis that the objects, properties and relations the world contains exist independently of our thoughts about them or our perceptions of them. Anti-realists either doubt or deny the existence of the entities the realist believes in or else doubt or deny their independence from our conceptions of them.

Some of the metaphysical issues over which realism and anti-realism have locked horns are the following: Are there moral values? Are there abstract objects like numbers or points or spaces or symphonies or jokes? What about selves or souls or minds? Are there colours? What of after-images, pains and other sensations? Is the past real? What of the future? Are fictional characters real? Do muons and quarks and other theoretical entities exist?

These represent only a small sample of current realist/anti-realist debates about the existence of certain sorts of entities or properties. Similar questions could be and have been raised about the mind-independence of the disputed entities or properties.

For example, many think that colours are mind-dependent. That is, whilst they do not dispute the existence of things that are red, green, blue etc., they think that if no sentient creatures had ever evolved nothing would have been coloured. The tomato's redness is, if not in the eye of the perceiver, non-existent without it. Others deem moral values mind-dependent. Once more, they do not doubt the existence of moral values but instead question their independence from the mind, believing them instead to be psychological or social constructs of some sort or other.

An obvious problem with this characterization of realism is that it seems to make anti-realism about

minds or experience obligatory! For the existence of minds is surely ‘mind-dependent’ and indeed it is in the sense that if there were no minds there'd be no minds and there'd be no experiences either.

This is not what is intended by the ‘mind-independence’ formulation, however. A realist about mental states or conscious experiences is one who holds that our world is a world containing creatures who are sometimes in states of believing, desiring, remembering, perceiving, etc. and that the world's containing (creatures who enjoy) such states is in no way dependent upon the ability of those creatures themselves to determine, either conceptually or perceptually, that it does. The world is as it is independently of what we think about it.

This characterization of realism is not universally accepted. Some anti-realists maintain that realism is committed to a distinctive (and tendentious) conception of truth [Compare Putnam 1981, 1985, 1992] or, more radically, that realism just is a thesis about the nature of truth - that truth can transcend the possibility of verification [Compare Dummett 1978, 1991, 1993].

These semantic formulations of realism are unacceptable to realists who are deflationists about truth [see the entry truth: deflationary theory of] however with the unfortunate consequence that many such realists tend to simply ignore the anti-realist's legitimate semantic challenges to their position. For deflationary theories of truth deny that truth is a substantive notion which can be used to characterise alternative metaphysical views.

Some examples may help to illustrate the mind-independence characterization. Most of us are realists about elephants. We believe the world contains elephants and that its containing them is in no way dependent upon our having perceived them or thought about them.

What about Yeti? Yeti realism is nowhere near as persuasive as pachyderm realism. Yes, there are lots of stories about large woolly ape-men hiding in the recesses of the Himalayas and occasionally interacting with humans (scaring them, mainly), but we're not sure what status to accord those stories. May be they are veridical observations of some enormous rare ape mistaken for an ‘ape- man’ or may be just erroneous observations of sociopaths in Yak coats? Alternatively, these supposed ‘sightings’ might simply be stories Tibetans tell their children.

If Yeti reports were to prove credible as reports and definite enough we might decide that we knew what it would take for a creature to be a Yeti and, after an exhaustive search, that the world contained no such creatures or admit, in the absence of any such search, that the world might well contain Yeti, and that whether it does or doesn't in no way depends upon our speculations on the matter.

We would be Eliminativists about Yeti if we decided that the world contained none, adopting an Error Theory towards the reports of Yeti, alleging some perceptual or other type of error behind them. We would be agnostic about Yeti if we decided that though the reports may be veridical and there may well be such creatures, there was as of now no good reason to believe there are any.

Suppose, on the other hand, that all we ever will have are the vague Yeti legends we now have. In that circumstance we might wonder whether the ‘sightings’ were even supposed to be reports. Perhaps the Yeti stories are like Santa Claus stories -- not intended to be taken literally? Their function might be to chasten obstreperous Tibetan children just as Santa Claus stories function to reward good Western children -- even though, naturally, both stories can only discharge their roles if the children mistakenly believe they are factual. If this was our assessment, we'd be taking a Non-Factualist attitude to Yeti stories. The function of such stories is not to describe reality.

Most of us are Eliminativists about Yeti. We think there aren't any. This is because we either think that the reports are erroneous or that the ‘sightings’ are not meant to be taken literally. Those who are agnostic about Yeti take a more charitable attitude to the reports -- they think that the world may well contain the sort of creature described therein. This sounds pretty unlikely to most ears. That's why we're Yeti Eliminativists for the most part and not Yeti Agnostics.

One thing we don't think is that it would never be rational to believe any report of a Yeti. To the contrary. The discovery of some huge new hairy ape by a team of reputable scientists in roughly the right vicinity should certainly lead us to reassess our Non-Factualist attitudes to Yeti reports. Given the indeterminacy of our ‘Yeti specifications’, such a discovery would still leave it open whether the creature was a Yeti. A more temperate conclusion would be that it had spawned the (rather fanciful)Yeti stories.

What of a new hairy hominid? This could very plausibly be a Yeti since the stories all agree that the Yeti is an ape-man. Still we would need further information before rushing to claim it was. Perhaps this hominid had never been seen before its discovery by the scientists and the legends were all based on perceptual errors of the sort canvassed above? It would just be a fluke that this creature fitted the descriptions. Homo Himalayus might then be called ‘Yeti’ by the scientists as a way of paying deference to the legends, rather than vindicating their authenticity.

This provides a contrast with the anti-realist views to be discussed below. They do think that it would never be rational to believe in the existence of the mind-independent entities the realist believes in. No evidence could convince us that some entity existed mind-independently because the very idea of mind-independent existence is incoherent.

We should note, though, that anti-realism is not intrinsically a global view. One may be a realist about certain domains and an anti-realist about others. Indeed it is not uncommon for scientific realists to be ethical anit-realists since many such thinkers hold that whilst black holes and baby universes may be mind-independent, moral values and norms are distinctively human constructions.

2. Realism and Factualism

It is often claimed that realism is a thesis about discourses or theories -- that the sentences in some discourse or theory are to be construed literally as fact- stating ones. This is factualism. It is often added that what these sentences state is largely true, although this is not a requirement of factualism per se.

It is a mistake to identify realism with factualism, however. The anti-realist views to be discussed below are factualist about the discourses describing certain contentious domains. What they contest is that the entities in these domains exist mind-independently as they find the notion of mind-independent existence incoherent.

Amongst views that generally accept the notion of mind-independent existence, a selective realism about Fs vies with selective eliminativism and agnosticism as answers to the question “Does the world contain Fs?” The realist says “Yes”, the eliminativist says “No”, the agnostic says “We can't say”. All three views agree that the existence of Fs in no way depends upon our ability to determine that they exist.

Some anti-realists agree that there are Fs but deny that anything could exist mind-independently. Unlike eliminativists and agnostics who accept it, they reject the notion of mind-independent existence. They are factualists about F discourse and anti-realist about Fs. However, such anti-realists differ from realists in their understanding of ‘Fs exist’ and, as a result, their interpretation of F discourse in general varies from that of the realist's.

Clearly, adopting a non-factualist or error-theoretic interpretation of discourse about Fs commits one to anti-realism about Fs. If we think Yeti reports are systematically mistaken or that such reports are not meant to be taken literally in the first place, we will deny that the world contains any Yetis. This means factualism is a necessary condition for realism.

It is not a sufficient condition though. Verificationists who reject the idea that something might exist even though we might never be able to confirm that it did, can be factualists about F discourse. Still, they are anti-realist about Fs since they deny that Fs could exist mind-independently.

Realism about a given class of entities may entail that discourse about them is factual but it certainly does not entail that most of our assertions concerning them are true. To the contrary, all our claims about the relevant domain could be mistaken. Consider mediaeval discourse about the cosmos. The mediaevals surely did believe that the cosmos was as it was, independently of what anyone thought about it. They were realists about the cosmos. Yet most of their beliefs were false, not true.

3. The Problem of Representation

Realism is a metaphysical thesis about what the world is like, what it contains. It is not a semantic thesis concerned with how humans represent the world in thought or language. How can it then be vulnerable to semantic challenge?

Quite simply. If the world is as resolutely mind-independent as the realist makes out, there is a problem about how we get to know about it in the first place. On what grounds can we trust our theories if they could all be radically mistaken? Wouldn't a truly mind-independent world make any representation of it in thought or language unreliable or even impossible? These are precisely the questions anti-realist urge in

their various semantic challenges to realism.

Realists do think, in the main, that we are able to represent the world reliably. Scientific realists think science is the best representation that we have of what the world is like and that its representations correspond pretty closely to the way things actually are. Yet it is crucial to their position that even our best scientific theories -- General Relativity, Quantum Theory, Theory of Evolution etc. -- could be radically mistaken. Be that as it may, when scientists talk about muons and quarks, gravitational constants, entropy, quantum fluctuations, the curvature of space-time etc. they are not just exploiting some useful linguistic devices for organizing their observational data, they are telling us what the world contains, independently of what anyone might think it contains, according to scientific realists.

For the scientist's representations of the world to be reliable, there must be a correlation between these representations and the states of affairs which they portray. So the cosmologist who utters the statement ‘The entropy of the Big Bang was remarkably low’ has uttered a truth if and only if the entropy of the Big Bang was remarkably low.

A natural question to ask is how the correlation between the statement and the mind-independent state of affairs which makes it true is supposed to be set up. How does it come about that the word ‘entropy’ refers to the amount of disorder in a system, that the descriptive name ‘The Big Bang’ refers to the event with which the Universe began? Is it that the shock waves of that cataclysmic event continue to reverberate some sixteen billion years later in human minds, dislodging a mental symbol as if it were a loose tooth, and that this mental symbol refers to whatever it was that shook it free? Clearly not. How then does that mental symbol get to refer to the Big Bang?

The only plausible answer has to do with us as cognitive beings. It is something about the way we use our words or deploy our mental symbols in thought and action which effects this correlation between mental symbol and worldly referent.

Suppose this is not so. Assume instead that God or Nature has solved this problem for us. God or Nature has set up just the right connections between our mental symbols and the bits of the world which we take ourselves to be referring to in thought.

Still we face the problem of finding evidence that this has occurred. Yet it seems the relevant evidence will be just what it was if God or Nature had not been so obliging -- linguistically, it will be the use speakers make of their words, the statements they endorse and the statements they dissent from, the rationalizations they provide for their actions, their defence and explanations of their views and criticisms of opposing views etc.; cognitively, it will be the functional role of mental symbols in thought, perception, language learning etc.

4. The Semantic Challenges to Realism

Manifestation

The first anti-realist challenge to consider focuses on the use we make of our words and sentences. The challenge is simply this: what aspect of our linguistic use could provide the necessary evidence for the realist's correlation between sentences and mind-independent states of affairs? Which aspects of our semantic behaviour manifest our grasp of these correlations, assuming they do hold?

When we look at how speakers actually do use their sentences, anti-realists claim, we see them responding not to states of affairs that they cannot in general detect but rather to agreed upon conditions for asserting these sentences. Scientists assert ‘The entropy of the Big Bang was remarkably low’ because they all concur that the conditions justifying this assertion have been met.

What prompts us to use our sentences in the way that we do are the public justification conditions associated with those sentences, justification conditions forged in linguistic practices which imbue these sentences with meaning.

The realist believes we are able to mentally represent mind-independent states of affairs. But what of cases where everything that we know about the world leaves it unsettled whether the relevant state of affairs obtains? Did Socrates sneeze in his sleep the night before he took the hemlock or did he not? How could we possibly find out? Yet realists hold that the sentence ‘Socrates sneezed in his sleep the night before he took the hemlock’ will be true if Socrates did sneeze then and false if he did not and that this is a significant semantic fact.

The Manifestation challenge to realism is to isolate some feature of the use agents make of their words or their mental symbols which effects the link between mind-independent states of affairs and the thoughts and sentences that represent them. Nothing in the thinker's linguistic behaviour, according to the anti-realist, provides evidence that this link has been forged since linguistic use is keyed to public assertibility conditions, not undetectable truth- conditions. In those cases, such as the Socrates one, where we cannot find out whether the truth-condition is satisfied or not, it is simply gratuitous to believe that there is anything we can think or say or do which could provide evidence that the link has been set up in the first place. So the anti-realist claims. [Compare Dummett 1978, 1991, 1993 Tennant 1997; Wright 1993.]

Why should we expect the evidence to be behavioural rather than, say, neurophysiological? The reason anti-realists give is that the meanings of our word and (derivatively for them) the contents of our thoughts are essentially communicable and thus must be open for all speakers and thinkers to see [Dummett 1978, 1993]

An interesting question arises as to whether our linguistic dispositions suffice to determine what we mean by our words. Saul Kripke has argued, on behalf of Wittgenstein, that the answer to this is ‘No’ -- that there are simply no facts that correspond to one's meaning Yeti by the word ‘Yeti’ irrespective of whether these facts are restricted to the behavioural. The resultant meaning scepticism has been argued by some to lead to a very radical global anti-realism which is dubiously coherent [Boghossian 1989, Wright 1984].

Language Acquisition

The second challenge to be considered concerns our acquisition of language. Suppose God had linked our mental representations to just the right states of affairs in the way required by the realist. If so, this is a semantically significant fact. Anyone learning their native language would have to grasp these correspondences between sentences and states of affairs. How can they do this if even the competent speakers whom they seek to emulate cannot detect when these correspondences hold? In short, competence in one's language would be impossible to acquire if realism were true. [Compare Dummett 1978, 1993; Wright 1993.]

Brains in a Vat?

States of affairs that are truly mind-independent go hand in glove with radical scepticism. The sceptic contends that for all we could tell we could be Brains in a Vat -- brains kept alive in a bath of nutrients by mad alien scientists. All our thoughts, all our experience, all that passed for science would be systematically mistaken if we were. We'd have no bodies although we thought we did, the world would contain no physical objects, yet it would seem to us that it did, there'd be no Earth, no Sun, no vast universe, only the brain's deluded representations of such. At least this could be the case if our representations derived even part of their content from links with mind-independent objects and states of affairs. Since realism implies such an absurd possibility could hold without our being able to detect it, it has to be rejected according to anti- realists.

A much stronger anti-realist argument uses the Brain in a Vat hypothesis to show that realism is internally incoherent rather than, as before, simply false. A crucial assumption of the argument is Semantic Externalism -- the thesis that the reference of our words and mental symbols is partially determined by contingent relations between thinkers and the world. This is a semantic assumption many realists independently endorse.

Given Semantic Externalism, the argument proceeds by claiming that if we were brains in a vat we could not possibly have the thought that we were. For, if we were so envatted, we could not possibly mean by ‘brain’ and ‘vat’ what unenvatted folk mean by these words since our words would be connected only to neural impulses or images in our brains where the unenvatteds' words are connected to real-life brains and real-life vats. Similarly the thought we pondered whenever we posed the question ‘Am I a Brain in a Vat?’ could not possibly be the thought unenvatted folk pose when they ask themselves the same-sounding question in English. But realism entails that we could indeed be Brains in a Vat. As we have just shown that were we to be so, we could not even entertain this as a possibility, realism is incoherent. [Compare Putnam 1981.]

Conceptual Relativity

If the notion of mind-independent existence is incoherent, as anti-realists contend, what should we put in

its stead? Berkeley famously answered “Mind- dependent existence!” where the Mind in question, for the good Bishop, was, of course, the Mind of God. Modern anti-realists tend not to be theists and tend not to relativize existence to any single mind. Instead of God they posit conceptual schemes as that on which the notion of existence depends. To that extent they follow Kant rather than Berkeley, though unlike Kant they tend to be pluralists -- it is conceptual schemes which they endorse rather than The One Conceptual Scheme which Kant held to be obligatory for all rational creatures.

According to this view, there can no more be an answer to the question “What objects and properties does the world contain?” outside of some scheme for classifying entities than there can be an answer to the question of whether two events A and B are simultaneous outside of some inertial frame for dating those events. The objects which exist are the objects some conceptual scheme says exists. ‘mesons exist’ really means ‘mesons exist relative to the conceptual scheme of current physics’.

Realists think there is a unitary sense of ‘object’, ‘property’ etc. for which the question ‘What objects and properties does the world contain?’ makes sense. Any answer which succeeded in listing all the objects, properties, events etc. which the world contains would comprise a privileged description of that totality. Anti-realists reject this. For them ‘object’, ‘property’ etc. shift their senses as we move from one conceptual scheme to another. Some anti-realists argue that there cannot be a totality of all the objects the world contains since the notion of ‘object’ is indefinitely extensible and so, trivially, there cannot be a privileged description of any such totality.

How does the anti-realist defend conceptual relativity? By arguing that there can be two complete theories of the world which are descriptively equivalent yet logically incompatible from the realist's point of view. For example theories of space-time can be formulated in one of two mathematically equivalent ways: either with an ontology of points, spatiotemporal regions being defined as sets of points or with an ontology of regions, points being defined as convergent sets of regions. Such theories are descriptively equivalent since mathematically equivalent and yet are logically incompatible from the realist's point of view, anti-realists contend. [Compare Putnam 1985, 1990.]

The Model-Theoretic Argument

This is the most technical of the arguments we have so far considered although we shall not reproduce the technicalities here - the central ideas can be conveyed informally, although some technical concepts will be mentioned where necessary. The argument purports to show that the Problem of Representation introduced before is insoluble for realists. That problem, to recall, was to explain how our mental symbols and words get hooked up to mind-independent objects and how our sentences and thoughts target mind-independent states of affairs.

According to the Model-Theoretic Argument, there are simply too many ways in which our mental symbols can be mapped onto items in the world. A consequence of this is that realists must either accept massive indeterminacy in what our symbols refer to or insist dogmatically that even an ideal theory, whose terms and predicates can demonstrably be mapped onto objects and properties of some sort in the

world so as to make its theses come out true might still be false, i.e. that such a mapping might not be the right one, the one ‘intended’.

Neither alternative can be defended, according to anti-realists. Massive indeterminacy in perfectly determinate terms is absurd, whilst for realists to contend that even an ideal theory could be false is to resort to dogmatism, since on their own admission we cannot tell which mapping the world has set up for us. Such dogmatism leaves the realist with no answer to a scepticism which undermines any capacity to reliably represent the world, anti-realists maintain.

Why can't an ideal theory be false? To admit that this is possible is to admit that there is a gap between what is true and what is ideally warranted by our best theory, something no anti-realist can afford to do. But an argument is needed to show this is not possible.

Anti-realists have one in the Model-Theoretic Argument. It proceeds thus: We imagine that we have an ideal theory T which passes every observational and theoretical test we can conceive of. Assume we can formalize T in first order logic. Assume also that the world is infinite in size and that our formal theory T is consistent. Then by the Completeness Theorem for first order logic, T will have a model M of the same size as the world (since by that theorem T will have models of every infinite size). Match up the objects in the model M one to one with the objects the world contains and use this mapping to define the relations of M directly in the world. We now have a correspondence between the expressions of the language L in which T is expressed and (sets of) objects in the world. T will then be true if ‘true’ just means ‘true-in-M’.

If T is not guaranteed true by this procedure it can only be because M is not the intended model. Yet all our observation sentences come out true according to M and the theoretical constraints must be satisfied because T's theses all come out true in M also. So the realist owes us an explanation of what constraints a model has to satisfy for it to be ‘intended’ over and above its satisfying every observational and theoretical constraint we can conceive of. Suppose on the other hand that the realist is able to somehow specify the intended model. Call this model M*. Then nothing the realist can do can possibly distinguish M* from a permuted variant P which can be specified following Putnam 1994b, 356-357:

We define properties of being a cat* and being a mat* such that:
(i) In the actual world cherries are cats* and trees are mats*
(ii) In every possible world the two sentences "A cat is on a mat" and "A cat* is on a mat*" have precisely the same truth value.
Instead of considering two sentences "A cat is on a mat" and "A cat* is on a mat*" now consider only the one "A cat is on a mat", allowing its interpretation to change by first adopting the standard interpretation for it and then adopting the non-standard interpretation in which the set of cats* are assigned to ’cat’ in every possible world and the set of mats* are assigned to ’mat’ in every possible world. The result will be the truth-value of "A cat is on a mat" will not change and will be exactly the same as before in every possible world. Similar non-standard reference assignments could be constructed for all the predicates of a language. [Compare Putnam 1985, 1994b.]

5. Realist Responses

We now turn to some realist responses to these challenges. The Manifestation and Language Acquisition challenges allege there is nothing in an agent's cognitive or linguistic behaviour that could provide evidence that they had grasped what it was for a sentence to be true in the realist's sense of ‘true’. How can you manifest a grasp of a notion which can apply or fail to apply without you being able to tell which? How could you ever learn to use such a concept?

One possible realist response is that the concept of truth is actually a very simple one and the demand that one always be able to determine whether a concept applies or fails to apply spurious. As to the first part, it is often argued that all there is to the notion of truth is what is given by the formula “’p’ is true if and only if p”. The function of the truth-predicate is to disquote sentences in the sense of undoing the effects of quotation -- thus all that one is saying in calling the sentence ‘Yeti are vicious’ true is that Yeti are vicious.

It is not clear that this response really addresses the anti-realist's worry, however. It may well be that there is a simple algorithm for learning the meaning of ‘true’ and that, consequently, there is no special difficulty in learning to apply the concept. But that by itself does not tell us whether the predicate ‘true’ applies to cases where we cannot ascertain that it does. All the algorithm tells us, in effect, is that if it is legitimate to assert p it is legitimate to assert that ‘p ‘ is true. So are we entitled to assert ‘Either Socrates did or did not sneeze in his sleep the night before he took the hemlock’ or are we not? Presumably that will depend on what we mean by the sentence, whether we mean to be adverting to two states of affairs neither of which we have any prospect of ever confirming.

Anti-realists follow verificationists in rejecting the intelligibility of such states of affairs and tend to model their rules for assertion on intuitionistic logic which rejects the universal applicability of the Law of Bivalence, the principle that every statement is either true or false. This law is a foundational semantic principle for classical logic.

As to the analogy with vagueness, this is a little more involved. If one accepts the Epistemic conception of vagueness then one will hold that a ‘penumbral’ case of red could indeed be red even though we could not in principle determine that it was. Since this is precisely how the realist thinks of truth, as applying or not independently of our capacity to determine this, the analogy would be apt. But the Epistemic theory of vagueness is highly controversial and other theories of vagueness deny that borderline red surfaces must either be red or not. Perhaps the realist could then link the two theories, claiming that since there is no incoherence in the Epistemic interpretation of vagueness, there is no incoherence in the realist notion of truth? Predictably, though, the anti- realist will reply that if these two theories really must stand or fall together, then they fall together.

A more direct realist response to the Manifestation challenge points to the prevalence in our linguistic practices of realist-inspired beliefs which we give expression to in what we say and do. The fact is that we do assert things like ‘Elephants exist independently of what anyone believes’ and all our actions and other

assertions confirm that we really do believe this. For example, we all agree that even if humans had never evolved on this planet the world could still have contained elephants. Furthermore, the overwhelming acceptance of classical logic by mathematicians and scientists and their rejection of intuitionistic logic for the purposes of mainstream science provides very good evidence for the coherence and usefulness of a distinctively realist understanding of truth.

Anti-realists reject this reply. They argue that all we make manifest by asserting things like ‘Either Socrates sneezed in his sleep the night before he took the hemlock or else he didn't’ is our pervasive misunderstanding of the notion of truth. They apply the same diagnosis to our belief in the mind-independence of elephants and to the counterfactual above which expresses this belief. We overgeneralize the notion of truth, believing that it applies in cases where it does not. A consequence of their view is that reality is indeterminate in surprising ways -- we have no grounds for asserting that Socrates did sneeze in his sleep the night before he took the hemlock and no grounds for asserting that he did not and no prospect of ever finding out which. Does this mean that for anti-realist the world contains no such fact as the fact that Socrates did one or the other of these two things? Not necessarily. For anti-realists who subscribe to intuitionistic principles of reasoning, the most that can be said is that there is no present warrant to assert that Socrates either did or did not sneeze in his sleep the night before he took the hemlock.

Perhaps anti-realists are right about all this. But if so, they need to explain how a practice based on a pervasive illusion can be as successful as modern science is. The fact is that anti-realists perturbed by the manifestability of realist truth are revisionists about parts of our linguistic practice and the consequence of this revisionist stance is that mathematics and science require extensive and non-trivial revision.

Much could be and has been said by anti-realists in response to this point. Standing back from the debate between the two sides is not always easy but at least this point should be made. Nothing said so far solves the Representation Problem, the problem of how our mental symbols get to target mind-independent entities in the first place, let alone the right ones. Some natural mechanism for effecting the right links must be at work for it cannot just be a primitive inexplicable fact that ‘The Big Bang’ refers to the Big Bang. If this problem could be solved, the Manifestation and Acquisition challenges would, presumably, be answered. It is, of course, the burden of the other anti-realist challenges to show that the realist cannot solve the Representation Problem.

Brains in a Vat

Realists who are naturalistic in their thinking are perhaps better placed than others to respond to this particular challenge. Recall that the Brain in a Vat argument purports to show that realism is incoherent on the grounds that it is both committed to the genuine possibility of our being Brains in a Vat and yet entails something inconsistent with this: namely, that were we to be so envatted we could not possibly have the thought that we were!

Realists have two obvious responses. They may either forswear commitment to Brains in a Vat or else

deny the Semantic Externalism which allegedly implies we could not think that we were Brains in a Vat were we to be so.

Naturalistic realists do question the coherence of the very idea of our being Brains in a Vat. For them there is no external vantage point from which one can assess our best overall theory and yet the sceptic's hypothesis feigns to occupy just such a vantage point. How so? By using terms which derive their meaning from successful theory to pose a problem which, if intelligible, would rob those very terms of meaning. In a similar vein some naturalistic realists have claimed that the mad scientists face an insoluble problem of combinatorial explosion the moment they give you any significant exploratory and volitional powers in the virtual world in which you are imprisoned.

As to the latter, it may be that the clever alien scientists have generated a convincing illusion of significant exploratory and volitional powers in the mind of the poor envatted Brain. Whether the sceptic's prospect is intelligible only at the cost of robbing the very terms in which it is framed of meaning is much more difficult to assess, however.

What of denying Semantic Externalism? Is this really a live option for realists? The answer is ‘Yes’. There are many realists who think the Representation Problem is just a pseudo-problem. When we say things like “’cat’ refers to cats” or “’quark’ refers to quarks” we are simply registering our dispositions to call everything we consider sufficiently cat-like/quark-like, ‘cat’/’quark’. According to these Semantic Deflationists, it is just a confusion to ask how the link was set up between our use of ‘The Big Bang’ and the event of that name which occurred some sixteen billion years ago. Some naturalistic story can, presumably, be told about how creatures like us developed the linguistic dispositions we did, in the telling of which it will emerge how we come to assert things like ‘The entropy of the Big Bang was very low’.

It is a moot question whether Semantic Deflationism really dissolves the Representation Problem or merely refuses to face up to it, though. However the story about the origins of our linguistic dispositions is told, it had better be that our utterances of ‘The entropy of the Big Bang was very low’ somehow end up evincing just the right sort of differential sensitivity to the Big Bang's having low entropy. For if all there is to the story are our linguistic dispositions and the conditions to which they are presently attuned, the case has effectively been ceded to the anti-realist who denies it is possible to set up a correlation between our utterances or thoughts and the mind-independent states of affairs which uniquely make them true.

A different response questions the implementation of Externalist constraints in the argument. It may well be that if we were Brains in a Vat we could not express the thought the unenvatted express when they say ‘we might be Brains in a Vat’ but this does not prove this thought is inexpressible tout court for such a Brain. Perhaps the Brain can contemplate the possibility of its own incarceration using some sophisticated indirect theoretical reasoning?

Realists in general see it as a fatal weakness of anti-realism that it does not permit fallible, finite creatures to be radically mistaken in the beliefs they form about the world. Many realists favourably disposed to Semanic Externalism do wish to hold both that we could indeed be Brains in a Vat and that even so we

could form the conjecture that we were. Of course the burden of proof is then placed on the realist to show how, compatibly with Externalism, the Brains can become aware of the possibility that they are envatted.

Realists influenced by Saul Kripke's views on metaphysics and epistemology might wish to argue that we do in fact know a priori that we are not brains in a vat. However, this is not because it is incoherent to suppose that we are. To the contrary, since we could have been brains in a vat the speculation that we in fact are is perfectly coherent. It is simply false. That we are not brains in a vat is thus a contingent a priori truth for such realists who see the brain-in-the-vat argument as conflating epistemological questions of what can be known a priori with metaphysical questions as to what is and is not genuinely possible. This response is all well and good privided we really can know a priori that we are not brains in a vat. Yet it is difficult to shake the doubt that we can know any such thing a priori - isn't it merely a better explanation of the actual course of our experience that we are not envatted?

At least this should be said. The anti-realists who reject the sceptic's thesis as unintelligible are not alone in doing this. Naturalistic realists often do as well. However, a demonstration that anti-realism alone can justifiably reject scepticism would be a very powerful point in its favour.

Yet it has to be said that the reasons anti-realists have so far offered for thinking they alone can confute the sceptic are not fully convincing. Either they give the hypothesis that I am a Brain in a Vat the same short shrift some naturalistic realists do, though for different reasons (having to do with the lack of assertibility conditions for the sentence ‘I am a Brain in a Vat’) or else they attempt to show that if I were a Brain in a Vat I'd be able to deduce that I am not since my utterances of ‘I am a Brain in a Vat’ would come out uniformly untrue. In the latter case, even if the conclusion is sustained by the reasoning (which is highly debatable) it is open to the realist to endorse it. So there is no ground at present for thinking that anti-realism alone can stave off radical scepticism as unintelligible.

Of course, anti-realists do not need to reject radical scepticism as unintelligible. They might join Kripkean realists in claiming that we know a priori that the brain-in-the-vat hypothesis is false.

Conceptual Relativity

To the extent that it seems to make the existence of all things relative to the classificatory skills of minds, the thesis of conceptual relativity looks highly counter-intuitive. Whilst it may be quite plausible to think that colours or moral values might disappear with the extinction of sentient life on Earth, it is not at all plausible to think that pachyderms and Yetis (if there are any) let alone trees, rocks and microbes would follow in their train! If our intuitions are anything to go by, then, the idea of conceptual relativity looks highly suspect.

Kant had a story to tell about why these intuitions were unreliable. This had to do with his distinction between empirical realism and transcendental idealism. According to the latter, our knowledge of what exists is nothing other than knowledge of how various objects appear to us. Of necessity, the knowing

mind cannot reach behind those appearances to how things are in themselves.

Dividing Kant's One True Conceptual Scheme into The Many suggested by modern anti-realists need not alter the basic distinction between how things are and how knowing minds represent them -- unless, of course, that distinction is itself questionable. In fact, many anti-realists do reject any such division, finding the whole idea of our being able to factor our knowledge of the world into separable contributions made by representational scheme and represented reality, quite objectionable. To them, Kant's problem with ‘noumena’ stems from a lingering, unrecognized attachment to realist metaphysics.

To the realist who complains that elephants would not cease to exist if humans vanished from the planet, the anti-realist should reply “Of course not!” To the contrary we accept a theory which licenses us to assert ‘Elephants exist’ and also licenses us to assert ‘If humans were to disappear from this planet, elephants need not follow in their train’ since the theory assures us that the existence of elephants in no way causally depends on the existence of humans. For the anti-realist the true picture is that our well-founded practices of assertion ground at one and the same time our conception of the world and our conception of humanity's place within it.

Realists are unlikely to be satisfied with this response, however. The worry is not so much that elephants might disappear, along with the rest of the mind- dependent world, with some plague that wiped out humanity but rather that whether there are to be any pachyderms in the first place apparently depends upon the conceptual schemes humans happen to chance upon! The relativity of existence to conceptual scheme is, in this respect, quite unlike the relativity of simultaneity to frame of reference.

Still, we have actual instances of conceptual schemes which explain the same phenomena equally well yet which are logically incompatible from the realist's point of view, anti-realists maintain. The earlier example of competing theories of space-time was a case in point. Recall that according to the first theory space-time consists of unextended spatiotemporal points and regions of space- time were to be explained as sets of these points whilst according to the second space-time consists of extended spatiotemporal regions and points were merely logical constructions, identifiable with convergent sets of regions.

In order to assess such examples we need a criterion of descriptive equivalence. Anti-realists have suggested that two theories are descriptively equivalent if each theory can be interpreted in the other and both theories explain the same phenomena.

Realists reject the anti-realist claim that there are two descriptively equivalent logically incompatible theories in cases such as the space-time one. Within the context of the relative interpretation of the one theory within the other, all the two alternative constructions of points in terms of regions and regions in terms of points actually show, the realist will say, is that there is a systematic way of assigning a point space to a region space and vice versa.

Anti-realist respond that the two theories really are incompatible since the region theory denies that points are physical entities. It is very hard to see how the region theory and the point theory can be both descriptively equivalent and logically incompatible, however. For if we restrict ourselves to the topology

of space-time the punctate and the region theory are descriptively equivanlent in the sense that each can be translated into the other: points as convergent sets of regions, regions as sets of points. So it is hard to see how the two theories can be logically incompatible topologically.

Differences do emerge over the contents of space-time: the properties, relations and functions definable on space or time. For punctate theories may contain details that are not duplicated in the region theories: at the stroke of midnight Cinderella's carriage changes into a pumpkin - it is a carriage up to midnight, a pumpkin thereafter. According to the region-based theory which takes temporal intervals as its primitives, that's all there is to it. But if there are temporal points, instants, there is a further fact left undecided by the story so far - viz, at the moment of midnight is the carriage still a carriage or is it a pumpkin?

So does the region-based theory fail to recognize certain facts or are these putative facts merely artefacts of the punctate theory's descriptive resources, reflecting nothing in reality? We cannot declare the two theories descriptively equivalent until we resolve this question at least.

In general, then, realists either dismiss cases of apparent logical incompatibility between two descriptively equivalent rival theories as merely apparent or question the descriptive equivalence of the two theories.

The Model Theoretic Argument

If realism is to be tenable at all, it must be possible for even our best theories to be mistaken. So realists must reject the Model-Theoretic Argument which purports to show that this is not possible. Realists have responded to the argument by rejecting the claim that a model M of the hypothetical ideal theory T passes every theoretical constraint simply because all of the theory's theses come out true in it. For there is no guarantee, they claim, that terms stand in the right relation of reference to the objects to which M links them. To be sure, if we impose a ‘right reference constraint’ as another theoretical constraint, M (or some model based on it) can interpret this constraint in such a way as to make it come out true. But there is a difference between a model's making some description of a constraint come out true and its actually conforming to that constraint, realists insist.

For their part, anti-realists have taken realist's insistence on a right reference constraint to be ‘just more theory’. This is understandable since from their point of view what it is for a model to conform to a constraint C is for us to be justified in asserting that it does. Unfortunately, this has led to something of a stand-off. Realists think that anti-realists are refusing to acknowledge a clear and important distinction. Anti-realists think that realists are simply falling back on dogmatism at a crucial point in the argument.

Many have concluded from the apparent stalemate that this particular debate is dialectically intractable -- one either sides with the realists or the anti- realists, depending on whether one thinks of truth as the realist does or as the anti-realist does. This conclusion, which would put the argument beyond the pale of rational appraisal, is a little premature, though. There are ways of explaining and illustrating the crucial issues concerning constraint satisfaction that are intelligible to anti-realists, ways which do not appeal to any verification-transcendent notions.

The Permutation Argument presents a genuine challenge to any realist who believes in determinate reference. But it does not refute realism unless realism is committed to determinate reference in the first place and it is not at all obvious that a belief in the mind-independence of reality does commit the realist to determinate reference. Realist responses to this argument vary widely. At one extreme are the 'determinatists', those who believe that Nature has set up significant, determinate referential connections between our mental symbols and items in the world. They contend that all the argument shows is that the distribution of truth-values across possible worlds is not sufficient to determine reference.

At another extreme are 'indeterminatists', realists who concede the conclusion, agreeing that it demonstrates that word-world reference is massively indeterminate or 'inscrutable'. Some infer from this that reference could not possibly consist in correspondences between mental symbols and objects in the world. For them all that makes 'elephant' refer to elephants is that our language contains the word 'elephant'. This is Deflationism about reference.

In between these two extremes are those prepared to concede the argument establishes the real possibility of significant and surprising indeterminacy in the reference of our mental symbols but who take it to be an open question whether other constraints can be found which pare down the range of reference assignments to just the intuitively acceptable ones. On this view 'elephant' may partially refer to elephants according to one acceptable reference assignment and may partially refer to elephant-stages or undetached elephant parts according to other such assignments, but not refer, even partially, to quolls or quarks.

6. Summary

We have considered a number of semantic challenges to realism, the thesis that the objects and properties that the world contains exist independently of our conception or perception of them. On all fronts, debate between realists and their anti-realist opponents is still very much open. If realists could provide a plausible theory about how correspondences between mental symbols and the items in the world to which they refer might be set up, many of these challenges could be met. Alternatively, if they could explain how, consistently with our knowledge of a mind-independent world, no such correspondences are required to begin with, many of the anti-realist objections would fall away as irrelevant. In the absence of such explanations it is still entirely reasonable for realists to believe that the correspondences are in place, however, and there can, indeed, be very good evidence for believing this. Ignorance of Nature's reference-fixing mechanism is no reason for denying it exists.

For their part, anti-realists themselves need to say more than they have so far said about how mental and semantic content is grounded in linguistic and cognitive practice. It is not obvious that they have any satisfactory answer to their own Representation Problem -- how are correlations between mental symbols and mind-dependent objects set up? Merely gesturing in the direction of accepted practices for asserting sentences is no satisfactory answer to this question if it is simply assumed that the asserted sentences have determinate meanings. How does human intervention succeed where Nature fails?

The Deflationary Theory of Truth

According to the deflationary theory of truth, to assert that a statement is true is just to assert the statement itself. For example, to say that ‘snow is white’ is true, or that it is true that snow is white, is equivalent to saying simply that snow is white, and this, according to the deflationary theory, is all that can be said significantly about the truth of ‘snow is white’.

There are many implications of a theory of this sort for philosophical debate about the nature of truth. Philosophers often make suggestions like the following: truth consists in correspondence to the facts; truth consists in coherence with a set of beliefs or propositions; truth is the ideal outcome of rational inquiry. According to the deflationist, however, such suggestions are mistaken, and, moreover, they all share a common mistake. The common mistake is to assume that truth *has* a nature of the kind that philosophers might find out about and develop theories of. For the deflationist, truth has no nature beyond what is captured in ordinary claims such as that ‘snow is white’ is true just in case snow is white. Philosophers looking for the nature of truth are bound to be frustrated, the deflationist says, because they are looking for something that isn't there.

The deflationary theory has gone by many different names, including at least the following: the redundancy theory, the disappearance theory, the no-truth theory, the disquotational theory, and the minimalist theory. There is no terminological consensus about how to use these labels: sometimes they are used interchangeably; sometimes they are used to mark distinctions between different versions of the same general view. Here I will use ‘deflationism’, and ‘the deflationary theory of truth’ to denote the general view I want to discuss, and reserve other names for specific versions of that view.

History of Deflationism

The deflationary theory has been one of the most popular approaches to truth in the twentieth century, having received explicit defense by Frege, Ramsey, Ayer, and Quine, as well as sympathetic treatment from many others. (According to Dummett 1959, the view originates with Frege.) The following passages all contain recognizable versions of the doctrine, though they differ on points of detail.

> It is worthy of notice that the sentence 'I smell the scent of violets' has the same content as the sentence 'it is true that I smell the scent of violets'. So it seems, then, that nothing is added to the thought by my ascribing to it the property of truth. (Frege 1918)

> Truth and falsity are ascribed primarily to propositions. The proposition to which they are ascribed may be either explicitly given or described. Suppose first that it is explicitly given; then it is evident that 'It is true that Caesar was murdered' means no more than that Caesar was murdered, and 'It is false that Caesar was murdered' means no more than Caesar was not murdered. They are phrases which we sometimes use for emphasis or stylistic reasons, or to indicate the position occupied by the statement in our argument....In the second case in which the proposition is described and not given explicitly we have perhaps more of a problem, for we get statements from which we cannot in ordinary language eliminate the words 'true' or 'false'. Thus if I say 'He is always right', I mean that the propositions he asserts are always true, and there does not seem to be any way of expressing this without using the word 'true'. But suppose we put it thus 'For all p, if he asserts p, p is true', then we see that the propositional function p is true is simply the same as p, as e.g. its value 'Caesar was murdered is true' is the same as' Caesar was murdered'. (Ramsey 1927)

> ...it is evident that a sentence of the form "p is true" or "it is true that p" the reference to truth never adds anything to the sense. If I say that it is true that Shakespeare wrote *Hamlet*, or that the proposition "Shakespeare wrote *Hamlet*" is true, I am saying no more than that Shakespeare wrote *Hamlet*. Similarly, if I say that it is false that Shakespeare wrote the *Illiad*, I am saying no more than that Shakespeare did not write the *Illiad*. And this shows that the words 'true' and 'false' are not used to stand for anything, but function in the sentence merely as assertion and negation signs. That is to say, truth and falsehood are not genuine concepts. Consequently there can be no logical problem concerning the nature of truth. (Ayer 1935).

> The truth predicate is a reminder that, despite a technical ascent to talk of sentences, our eye is on the world. This cancellatory force of the truth predicate is explicit in Tarski's paradigm:
>
> > 'Snow is white' is true if and only if snow is white.

> Quotation marks make all the difference between talking about words and talking about snow. The quotation is a name of a sentence that contains a name, namely ‘snow’, of snow. By calling the sentence true, we call snow white. The truth predicate is a device for disquotation. (Quine 1970).

In addition to being popular historically, the deflationary theory has been the focus of much recent work. Perhaps its most vociferous contemporary defenders are Hartry Field and Paul Horwich.

One reason for the popularity of deflationism is its anti-metaphysical stance. Deflationism seems to deflate a grand metaphysical puzzle, a puzzle about the nature of truth, and much of modern philosophy is marked by a profound scepticism of metaphysics. Another reason for the popularity of deflationism concerns the fact that truth is a semantic notion, and therefore takes its place along with other semantic notions, such as reference, meaning, and content. Many philosophers are concerned with trying to understand these semantic notions. The deflationary theory is attractive since it suggests that, at least in the case of truth, there is less to be puzzled about here than one might expect.

The Equivalence Schema

Perhaps because of the widespread interest in the deflationism, the theory has received many different formulations. The result is that there is not so much *a* deflationary theory of truth as many. In recent times, however, the deflationary theory has most often been presented with the help of a schema, which is sometimes called *the equivalence schema* (in this schema ‘n’ is a name for ‘p’):

> (ES) n is true if and only p.

With the help of (ES), we can formulate deflationism as the view, first, that someone has the concept of truth just in case he or she accepts all (nonparadoxical) instances of this schema, and, second, that saying this captures everything significant that can be said about truth. In most cases, theories which depart from deflationism don't deny the first part of this claim; what they deny is that the equivalence schema tells us the whole truth about truth. Since such theories *add* to the equivalence schema, they are often called *inflationary* theories of truth. (The equivalence schema is associated with Alfred Tarski (1944, 1958), but it is far from obvious that Tarski was any sort of deflationist. We will set Tarski aside here.)

Two important points need to be noted about this formulation of deflationism. The first point concerns the parenthetical word ‘nonparadoxical’. Why do we not say more simply that, according to deflationism, someone has the concept of truth just in case he or she accepts *all* instances of (ES). The reason is that some instances of the schema -- most notoriously, those associated with the liar paradox -- are either false or have no truth value, and are on that ground presumably would not be accepted by someone who has the concept of truth. We can mark these exceptions by restricting the formulation to nonparadoxical instances of the schema. (For further discussion of this issue, see the discussion of objection from truth value gaps below.)

The second point is that it is important to see that deflationists are not suggesting that the equivalence schema is an *explicit* definition of truth. First, (ES) is not a definition of anything. Second, the deflationary theory does not, strictly speaking, provide an explicit definition of truth at all. What the deflationary theory provides instead is an explicit definition of *having* the concept of truth. To be more precise, the suggestion of the deflationary theory is that someone has the concept of truth just in case he or she is disposed to accept all (noncontroversial) instances of the equivalence schema, i.e., every sentence of the form ‘n is true iff p’ that is not paradoxical or in some other way deviant. Of course, deflationists *do* think that, in saying something about what it is to have the concept of truth, they have told us what the concept of truth is. But the latter is a by-product of the former; for this reason, we can say that deflationists are proposing an *implicit* definition of the concept of truth. This marks an important divide between deflationist theories and other kinds of theories of truth which attempt to provide an explicit definition of truth in other terms.

Are there versions of deflationism, or positions allied to deflationism, which do not employ the equivalence schema or some similar device? Yes, but we shall mention them here only to set them aside. One such view-which may be called *expressivism* -- is the analogue of emotivism in ethics. (This view of truth is often associated with Strawson 1950, though the attribution is a difficult one.) According to emotivism, at least in one of its most traditional forms, utterances of the form ‘torture is wrong’ do not, despite appearances, predicate ‘is wrong’ of torture; rather utterances of ‘torture is wrong’ merely indicate a negative attitude on the part of the speaker toward torture. Expressivism is the parallel position about truth. According to expressivism, utterances of the form ‘S is true’ do not, despite appearances, predicate ‘is true’ of S; rather ‘S is true’ merely indicates preparedness on the part of the speaker to assert S.

Another such view is the *prosentential theory of truth* advanced by Dorothy Grover (see Grover, Camp and Belnap 1973, and Grover 1992) . According to this theory, sentences formed with the predicate ‘is true’ are *prosentences*, where a prosentence is a device for achieving anaphoric cross-reference to sentences uttered previously in a conversation, just as pronouns are devices for achieving anaphoric cross-reference to names uttered previously in a conversation. According to the prosentential theory, for example, just as in

> (1) Mary wanted to buy a car, but she could only afford a motorbike.

we interpret ‘she’ as a pronoun anaphorically dependent on ‘Mary’, so too in

> (2) Snow is white. That is true, but it rarely looks white in Pittsburgh

we interpret ‘That is true’ as a prosentence anaphorically dependent on ‘Snow is white’.

Expressivism and the prosentential theory are close cousins of deflationism, and, in some uses of the term, might reasonably be called deflationary. However, they are also sufficiently different from those versions of deflationism that utilize the equivalence schema to be set aside here. The important difference between expressivism and the prosentential theory on the one hand, and deflationism as we are

understanding it on the other, concerns the logical structure of sentences such as ‘S is true’. For the deflationist, the structure of such sentences is very straightforward: ‘’S’ is true’ predicates the property expressed by ‘is true’ of the thing denoted by ‘S’. We might express this by saying that, according to deflationism, ‘S is true’ says *of* S that it is true, just as ‘apples are red’ says, *of* apples, that they are red or ‘John sleeps’ says, *of* John, that he sleeps. Both expressivism and the prosentential theory deny this, though for different reasons. According to expressivism, ‘S is true’ is properly interpreted not even of subject-predicate form; rather it has the structure ‘Hooray to S’. Obviously, therefore, it does not say, *of* S, that it is true. According to prosententialism, by contrast, while ‘S is true’ has a subject-predicate structure, it would still be mistaken to interpret it as being about S. For consider: according to the prosentential theory, ‘S is true’ is a prosentence which stands in for the sentence denoted by S just as ‘she’ in (1) is a pronoun which stands in for the name ‘Mary’. But we do not say that ‘she’ in (1) is about the *name* ‘Mary’; similarly, according to the prosentential theory, we should not say that ‘S is true’ is about S. To suppose otherwise would be to misconstrue the nature of anaphora.

Varieties of Deflationism

Different interpretations of the equivalence schema yield different versions of deflationism.

One important question concerns the issue of what instances of the equivalence schema are assumed to be about (equivalently: to what the names in instances of the equivalence schema are assumed to refer). According to one view, instances of the equivalence schema are about sentences, where a name for a sentence can be formulated simply by quoting the sentence -- thus "’Brutus killed Caesar’" is a name for ‘Brutus killed Caesar’. In other words, for those who hold what might be called a *sententialist* version of deflationism the equivalence schema has instances like (3):

> (3) ‘Brutus killed Caesar’ is true if and only if Brutus killed Caesar.

To make this explicit, we might say that, according to sententialism, the equivalence schema is (ES-sent):

> (ES-sent) The sentence ‘s’ is true if and only if s

According to those who hold what might be called a *propositionalist* version of deflationism, by contrast, instances of the equivalence schema are about propositions, where names of propositions are, or can be taken to be, expressions of the form ‘the proposition that p’ -- thus, ‘the proposition that Brutus killed Caesar’ is a name for the proposition that Brutus killed Caesar. For the propositionalist, in other words, instances of the equivalence schema are properly interpreted not as being about sentences but about propositions, i.e., more like (4) than (3):

> (4) The proposition that Brutus killed Caesar is true if and only if Brutus killed Caesar.

To make this explicit, we might say that, according to propositionalism, the equivalence schema is (ES-

prop):

(ES-prop) The proposition that p is true if and only if p.

To interpret the equivalence schema as (ES-sent) rather than (ES-prop), or vice versa, is to yield a different deflationary theory of truth. Hence sententialism and propositionalism are different versions of deflationism. (There are also some further ways to interpret the equivalence schema, but we shall set them aside here.)

The other dimension along which deflationary theories vary concerns the nature of the equivalence that the theories interpret instances of the equivalence schema as asserting. On one view, the right hand side and the left hand side of such instances are analytically equivalent. Thus, for sententialists, (3) asserts that, "'Brutus killed Caesar' is true" means the same as 'Brutus killed Caesar'; while for propositionalists (4) asserts that 'the proposition that Brutus killed Caesar is true' means the same as 'Brutus killed Caesar'. A second view is that the right hand side and the left hand side of claims such as (3) and (4) are only materially equivalent; this view interprets the 'if and only if' in both (3) and (4) as the biconditional of classical logic. And a third view is that claims such as (3) and (4) assert a necessary equivalence between their right hand sides and their left hand sides; that is, both (3) and (4) are to be interpreted as material biconditionals that hold of necessity.

This tripartite distinction between analytic, necessary, and material equivalence, when combined with the distinction between sententialism and propositionalism, yields six different versions of deflationism:

	Sentential	Propositional
Analytic	A	B
Material	C	D
Necessary	E	F

It is this variegated nature of deflationism that to a large extent dictates the many names that have been used for the theory. The labels 'redundancy theory', 'disappearance theory' and 'no-truth theory' have been used mainly to apply to analytic versions of deflationism: positions A or B. The label 'disquotational theory' tends to apply to sententialist versions, and in fact to material sentential deflationism: position C. The label 'minimalist theory' is a label used recently by Paul Horwich (1990) to apply to necessary versions, and in fact to necessary propositional deflationism: position F. It will not be important for us to examine all of these versions of deflationism in detail; to a large extent philosophers prefer one or other versions of these views on the basis of views from other parts of philosophy, views about the philosophy of language and metaphysics. However, it will be convenient here to settle on one version of the view. I will therefore follow Horwich in concentrating mainly on position F. Horwich calls this view 'minimalism', but I will continue simply with 'deflationism'.

The Utility of Deflationary Truth

The deflationist idea that the equivalence schema (ES-prop) provides an implicit definition of the concept of truth suggests that truth is, as the label ‘redundancy theory’ suggests, a redundant concept, a concept that we could do without. On the contrary, however, advocates of the deflationary theory (particularly those influenced by Ramsey) are at pains to point out that anyone who has the concept of truth in this sense is in possession of a very useful concept indeed; in particular, anyone who has this concept is in a position to form generalizations that would otherwise require logical devices of infinite conjunction.

Suppose, for example, that Jones for whatever reason decides that Smith is an infallible guide to the nature of reality. We might then say that Jones believes everything Smith says. To say this much, however, is not to capture the content of Jones's belief. In order to do that we need some way of expressing an infinite conjunction of something like the following form:

> If Smith says that snow is white, then snow is white, and if he says snow is pink, then snow is pink, and if he says that snow is chartreuse, then snow is chartreuse,...and so on.

The equivalence schema (ES-prop) allows us to capture this infinite conjunction. For, on the basis of the schema, we can reformulate the infinite conjunction as:

> If Smith says that snow is white, then the proposition that snow is white is true, and if he says snow is pink, then the proposition that snow is pink is true, and if he says that snow is chartreuse, then the proposition that snow is chartreuse is true,...and so on.

In turn, this reformulated infinite conjunction can be expressed as a statement whose universal quantifier ranges over propositions:

> For every proposition x, if what Smith said = x, then x is true.

Or, to put the same thing more colloquially:

> Everything Smith says is true.

This statement give us the content of Jones's belief. And the important point for deflationists is that we could not have stated the content of this belief unless we had the concept of truth as described by the deflationary theory. In fact, for most deflationists, it is this feature of the concept of truth -- its role in the formation of generalizations -- that explains why we have a concept of truth at all. This is, as it is often put, the raison d'etre of the concept of truth.

Is Truth A Property?

It is commonly said that, according to the deflationary theory, truth is not a property and therefore that,

according to the theory, if a proposition is true, it is mistaken to say that the proposition has a property, the property of being true. There is something right and something wrong about this view, and to see what is wrong and right about it will help us to understand the deflationary theory.

Consider the two true propositions (5) and (6):

(5) Caracas is the capital of Venezuela

(6) The earth revolves around the sun.

Do these propositions share a property of being true? Well, in one sense of course they do: since they are both true, we can say that there both have the property of being true. In this sense, the deflationary theory is not denying that truth is a property: truth is the property that all true propositions have.

On the other hand, when we say that two things share a property F, we often mean more than simply that they are both F; we mean in addition that there is intuitively a common explanation as to why they are both F. It is in this second sense in which deflationists are denying that truth is a property. Thus, in the case of our example, what explains the truth of (5) is that Caracas is the capital of Venezuela; and what explains this is the political history of Venezuela. On the other hand, what explains the truth of (6) is that the earth revolves around the sun; and what explains this is the nature of the solar system. The nature of the solar system, however, has nothing to do with the political history of Venezuela (or if is does the connections are completely accidental!) and to that extent there is no shared explanation as to why (5) and (6) are both true. Therefore, in this stronger sense, they have no property in common.

It will help to bring out the contrast being invoked here if we consider two properties that have nothing to do with truth, the property of being, i.e. the property of having existence, and the property of being a mammal. Consider Hillary Rodham Clinton and the Great Wall of China. Do these objects have the property of existence? Well, in one sense, they do: they both exist so they both have the property of existence. On the other hand, however, there is no common explanation as to why they both exist. What explains the existence of the Great Wall is the architectural and defense policies of classical China; what explains the existence of Hillary Rodham Clinton is Mr and Mrs Rodham. We might then say that existence is not a property and mean by this that it does not follow from the fact that two things exist that there is a common explanation as to why they exist. But now compare the property of existence with the property of being a mammal. If two things are mammals, they have the property of being a mammal, but in addition there is some common explanation as to why they are both mammals-both are descended from the same family of creatures, say. According to deflationism, the property of being true is more like the property of existence than it is like the property of being a mammal, and this is what deflationists mean when they say that truth is not a property.

The Deflationary Theory of Falsity

Truth and falsity are a package deal. It would be hard to imagine someone having the concept of truth

without also having the concept of falsity. One obvious question to ask the proponent of the deflationary theory of truth, then, is how the theory is to be extended to falsity.

A natural account of the concept of falsity defines it in terms of the concept of truth. Thus, someone has the concept of falsehood just in case they accept instances of the schema:

> (F-prop) The proposition that P is false if and only if the proposition that P is not true

A second, and initially slightly different, account of falsity defines it directly in terms of negation. According to this view, someone has the concept of falsity just in case they accept instances of the schema:

> (F-prop*) The proposition that P is false if and only if it is not the case that P

Many deflationists suppose that that (F-prop) and (F-prop*) in fact implicitly define the same concept of falsity (cf Horwich 1994). The key idea here is that there seems no reason to distinguish *being true* from *being the case*. If there is no distinction between being true and being the case, presumably there is also no distinction between 'It is not the case that p' and 'It is not true that p'. In addition, however, 'It is not true that p' is plausibly synonymous with 'the proposition that p is not true'; and this means that (F-prop) and (F-prop*) are equivalent. As we will shortly see, this account of falsity, though certainly a natural one, leaves the deflationary theory open to an important objection concerning truth-value gaps.

Objections to Deflationism

Our concern to this point has been only with what the deflationary theory is. In the remainder of this article, I consider five objections. These are by no means the only objections that have been advanced against deflationism---Horwich (1990) considers thirty-nine different objections!---but they do seem particularly obvious and important.

Objection #1: Propositions Versus Sentences.

We noted earlier that deflationism can be presented in either a sententialist version or a propositionalist version. Some philosophers have suggested, however, that the choice between these two versions constitutes a dilemma for deflationism (Jackson, Oppy and Smith 1994). The objection is that if deflationism is construed in accordance with propositionalism, then it is trivial, but if it is construed in accordance with sententialism it is false. To illustrate the dilemma, consider the following claim:

> (7) *Snow is white* is true if and only if snow is white

Now, does *snow is white* refer to a sentence or a proposition? If, on the one hand, we take (7) to be about a sentence, then, assuming (7) can be interpreted as making a necessary claim, (7) is false. On the face of

it, after all, it takes a lot more than snow's being white for it to be the case that ‘snow is white’ is true. In order that ‘snow is white’ be true, it must be the case not only that snow is white, it must in addition be the case that ‘snow is white’ *means that* snow is white. But this is a fact about language that (7) ignores. On the other hand, suppose we take *snow is white* to denote a proposition; in particular, suppose we take it to denote the proposition that snow is white. Then the theory looks to be trivial, since the proposition that snow is white is defined as being true just in case snow is white. In short, the deflationist is faced with a dilemma: take deflationism to be a theory of sentences and it is false; take it to be a theory of propositions, on the other hand, and it is trivial.

Of the two horns of this dilemma, it might seem that the best strategy for deflationists is to remain with the propositionalist version of their doctrine and accept its triviality. A trivial doctrine, after all, at least has the advantage of being true. Moreover, the charge of triviality is something that deflationists might well be expected to wear as a badge of honor: since deflationists are advocating their theory as following from mundane facts about which everyone can agree, it is no wonder that the theory they advocate is trivial.

However, there are a number of reasons why deflationists have typically not endorsed this option. First, the triviality at issue here does not have its source in the concept of truth, but rather in the concept of a proposition. Second, a trivial version of deflationism says nothing about the theory of meaning, where by ‘theory of meaning’, I mean an account of the connections between sentences of natural language and the propositions they express. After all, if deflationists are attending only to propositions, they are evidently *not* attending to the relation between sentences and propositions. Of course, one might point out that other theories of truth are also silent on the theory of meaning-why then can deflationism not be? However, the fact is that many deflationists present their doctrine as a central part of a much bigger philosophical project, viz., to provide a deflationary account of all the semantic notions, that is, notions such as truth, reference, and meaning. The problem for deflationists who grasp the second horn of the dilemma is that they must admit that there is no way to complete this project: the deflationary theory of truth can only be maintained by remaining silent about the theory of meaning. And this means that deflationism should be understood as a much more modest project than it is often taken to be.

The other possible response to this dilemma is to accept that deflationism applies inter alia to sentences, but to argue that the sentences to which it applies must be *interpreted* sentences, i.e., sentences which have meaning. Of course, if the sentences to which deflationism applies are interpreted sentences, then there will be no force to the objection that deflationism is ignoring the fact that sentences have meaning. Deflationism, on this interpretation, is not so much ignoring this fact as *assuming* it.

However, if it is to be conceded that the deflationary theory of truth applies only to sentences which have meaning, the deflationist takes on a dual task: first, to provide some *other* account of what it is for a sentence to mean what it does; second, to provide an account that does not employ the concept of truth. For after all, if deflationists *did* appeal to the concept of truth in building their theory of meaning, the doctrine would be obviously circular. Since most theories of meaning do in fact appeal to the concept of truth, this task is by no means easy. However, recent defenders of deflationism have begun it: both Paul Horwich and Hartry Field have in different ways defended a version of a use theory of meaning (cf. Field

1994, Horwich 1995). There is, however, a lot of work to be done before a use theory can be regarded as a successful theory of meaning.

Objection #2: Correspondence

It is often said that what is most obvious about truth is that truth consists in correspondence to the facts-for example, that the truth of the proposition that the earth revolves around the sun consists in its correspondence to the fact that the earth revolves around the sun. The so-called correspondence theory of truth is built around this intuition, and tries to explain the notion of truth by appeal to the notions of correspondence and fact. Even if one does not *build* one's theory of truth around this intuition however, many philosophers regard it as a condition of adequacy on any theory of truth that the theory accommodates the correspondence intuition.

It is often objected to deflationism, however, that the doctrine has particular trouble meeting this adequacy condition. One way to bring out the problem here is by focusing on a particular articulation of the correspondence intuition, an articulation favoured by deflationists themselves (Horwich 1990). According to this way of spelling it out, the intuition that a certain sentence or proposition ‘corresponds to the facts’ is the intuition that the sentence or proposition is true *because* of a certain way the world is; that is, the truth of the proposition is *explained* by some contingent fact which is usually external to the proposition itself. We might express this by saying that someone who endorses the correspondence intuition so understood would endorse:

> (8) The proposition that snow is white is true *because* snow is white

Now, the problem with (8) is that, when we combine it with the deflationary theory-or at least with a necessary version of that theory-we can derive something that is plainly false. Someone who holds a necessary version of deflationism would clearly be committed to the necessary truth of:

> (9) The proposition that snow is white is true iff snow is white.

And, since (9) is a necessary truth, it is very plausible to suppose that (8) and (9) together entail:

> (10) Snow is white because snow is white.

Unfortunately, however, (10) is false. The reason is that the relation reported by ‘because’ in (8) and (10) is a causal or explanatory relation, and such relations must obtain between distinct relata. But the relata in (10) are (obviously) not distinct. Hence (10) is false. But this means that the conjunction of (8) and (9) must be false, and that deflationism is inconsistent with the correspondence intuition. To borrow a phrase of Mark Johnston's -- who mounts a similar argument in a different context -- we might put the point differently by saying that, if deflationism is true, then what seems to be a perfectly good explanation in (8) *goes missing*; if deflationism is true, after all, then (8) is equivalent to (10), and (10) is not an explanation of anything.

How might a deflationist respond to this objection? One response is to provide a different articulation of the correspondence intuition. For example, one might point out that the connection between the proposition that snow is white and snow's being white is not a contingent connection, and suggest that this rules out (8) as a successful articulation of the correspondence intuition. That intuition (one might continue) is more plausibly given voice by (8*):

> (8*) ‘Snow is white’ is true because snow is white.

However, when (8*) is conjoined with (9), one cannot derive the problematic (10), and thus, one might think, the objection from correspondence might be avoided. Now certainly this is a possible suggestion; the problem with it, however, is that a deflationist who thinks that (8*) is true is most plausibly construed as holding a sententialist, rather than a propositionalist, version of deflationism. A sententialist version of deflationism, on the other hand, will in turn supply a version of (9), viz.:

> (9*) ‘Snow is white’ is true iff snow is white

which, at least it is interpreted as a necessary truth, will conspire with (8*) to yield (10). And we are back where we started.

Another response would be to object that ‘because’ creates an opaque context -- that is, the kind of context within which one cannot substitute co-referring expressions and preserve truth. If ‘because’ creates an opaque context, then it would be illegitimate to suppose that (8) and (9) entail (10). This too is a possibility; however, it is not clear that ‘because’ creates opaque context of the right kind. In general we can distinguish two kinds of opaque context: intensional contexts, which allow the substitution of necessarily co-referring expressions but not contingently co-referring expressions; and hyper-intensional contexts, which do not even allow the substitution of necessarily co-referring expressions. If the inference from (8) and (9) to (10) is to be successfully blocked, it is necessary that ‘because’ creates a hyper-intensional context. However, it is open to a friend of the correspondence objection to argue that, while ‘because’ creates an intensional context, it does not create a hyper-intensional context.

A final, and most radical, response would be to reject the correspondence intuition outright. This response is not in fact as drastic as it sounds. In particular, the deflationist does not have say that someone who says ‘the proposition that snow is white corresponds to the facts’ is speaking falsely. Deflationists would do better to say that such a person is simply using a picturesque or ornate way of saying that the proposition is true, where truth is understood in accordance with the deflationary theory. Indeed, the deflationist can even agree that for certain rhetorical or conversational purposes, it might be more effective to use the ‘correspondence to the facts’ talk. Nevertheless, it is important to see that this response does involve a burden, since it involves rejecting a condition of adequacy that many regard as binding on a theory of truth

Objection #3: Truth-value Gaps.

Philosophy of language has isolated a class of propositions that are supposed to fail of truth-value. According to some moral philosophers, for example, moral propositions -- such as the injunction that one ought to return people's phonecalls -- are neither true nor false. The same thing is true, according to some philosophers of language, about propositions which presuppose the existence of something which does not in fact exist -- such as the claim that the present King of France is bald; about propositions that are vague -- such as the proposition that wall hangings are furniture; and about propositions that are paradoxical, such as those that arise in connection with the liar paradox. Let us call this thesis *the gap*, since it finds a gap in the class of propositions between those that have truth-values and those that don't.

The deflationary theory of truth is inconsistent with there being a gap in the class of propositions, and this has been thought by many to be an objection to the theory. The reason for the inconsistency is very simple, and flows directly from the deflationist theory of falsity that we considered earlier. Suppose, for reductio, that the gap is correct and thus that there is a proposition Q which lacks a truth-value. Obviously, since Q lacks a truth-value, it is not the case that it is true or false. But now consider the equivalence schema (F-prop):

> (F-prop) The proposition that P is false if and only if the proposition that P is not true.

It is clear from (F-prop) that if it is not the case that Q is true or false, then it is not the case that Q is true or not true. But that is a contradiction: it must be the case that Q is true or not true. It follows that Q must have a truth value, and, of course, that there is no gap in the class of propositions.

Clearly, then, one must give up, or modify, either deflationism or the gap. Which? One strategy modifies deflationism by jettisoning the account of falsity that the deflationist offers, while hanging on to the account of truth. This strategy is a fairly desperate one, however. To begin with, if we give up the account of falsehood, it is not clear that we have an account of truth. Truth and falsehood are, as I have said, a package deal. Moreover, the deflationary theories of falsity that we considered are motivated in large part by classical logic. Presumably, it would be desirable to maintain classical logic if at all possible, and this means that we should maintain the deflationist account of falsity. Finally, one can generate a problem for the gap even if we operate without falsity, and only with truth (Rescher 1969). Suppose, again for reductio, that there is a proposition Q that is neither true nor false. Obviously, if Q is neither true nor false, then the proposition that Q is true will be false. But this means that for at least one instance of the equivalence schema, one side of the biconditional will be false, and the other side will be neither true nor false. On all logics that involve truth-value gaps, however, such a biconditional will be counted either as false or else as neither true nor false. Either way, the result is that the equivalence schema is not true in all instances. And this contradicts deflationism.

A second strategy argues that the gap, as I have presented it, is malformed. According to this strategy, one should not respond to the phenomena that prompt the gap by suggesting that certain propositions lack truth values; one should rather suggest that certain declarative sentences lack truth values, i.e., because they fail to express propositions at all. Thus, if we take presupposition failure as our example, the suggestion is that instead of supposing that the *proposition* that the present King of France is bald does

not have a truth value if the King of France does not exist, one should rather suppose that the sentence ‘the present King of France is bald’ does not express a proposition, and therefore fails to have a truth value. This kind of approach removes any conflict between the gap and deflationism. The gap says, or implies, that certain sentences fail to express propositions; deflationism says, or implies, that if those sentences *did* express propositions, they would have truth values. But there is clearly no contradiction in supposing, on the one hand, that a certain sentence fails to express a proposition and, on the other, that if it did, it would have a truth value.

A final strategy is to reject the gap entirely, and to simply agree that there is no gap which divides either propositions or sentences. This may initially seem to be an overreaction to the inconsistency of deflationism and the gap; however, what lies behind this strategy is the thought that it is not clear that the various phenomena that motivate the gap ought to be regarded as phenomena which involve failure of truth value, whether of sentences or propositions. In the case of presupposition failure, for example, it is not clear that the problem is best explained by a failure of certain sentences to have truth values, or by the presence of conventional or conversational implicatures that govern utterances of those sentences. The possibility of a broadly pragmatic account of the phenomena suggests that one might accommodate the intuitions behind the gap without supposing that there is a gap in the class of propositions (for an example, see Stalnaker 1975).

Of course, at the present stage of investigation, both of these strategies are only schematic: it is not clear that both or either of them will be sufficient to account for the various linguistic phenomena that prompt the gap. Clearly, work is required on the part of deflationists to show that these strategies are in fact up to the task.

Objection #4: Normativity.

It is commonly said that our beliefs and assertions aim at truth. The idea here, of course, is not that our beliefs and assertions are always true in a statistical sense, or even that they are mostly true. The idea is rather that truth is a *norm* of assertion. This fact about assertion and truth has often been seen to suggest that deflationism must be false. However, the felt contradiction between normativity and deflationism is difficult to make precise.

The first thing to say is that there is certainly a sense in which deflationism is not inconsistent with the idea that truth is a norm of assertion. To illustrate this, notice that we can obtain an intuitive understanding of the content of this idea without mentioning truth at all, so long as we focus on a particular case. Suppose for whatever reason that Mary sincerely believes that snow is green, has good evidence for this belief, and on the basis of this belief and evidence asserts that snow is green. We might say that there is a norm of assertion which implies that Mary is in this case open to criticism. After all, since snow is evidently not green, there must be something *incorrect* or *defective* about Mary's assertion that it is. It is this incorrection or defectiveness that the idea that truth is a norm of assertion is trying to capture.

But now let us see if we can give a general statement of the norm that lies behind this particular case. The problem of providing a general statement seems to be difficult, and for reasons that by now should be familiar. To state the norm in general we would need to be able to do something we cannot really do, namely, to complete an infinite conjunction of something like the following form:

> If someone asserts that snow is green, and snow is not green then he or she is open to criticism, and if someone asserts that grass is purple, and grass is not purple then he or she is open to criticism,...and so on.

Given the equivalence schema (F-prop*) provided by the deflationary theory of falsity, however, this infinite conjunction can be reformulated as:

> If someone asserts that snow is green and the proposition that snow is green is false, then he or she is open to criticism, and if someone asserts that grass is purple and the proposition that grass is purple is false, then he or she is open to criticism, and so on.

In turn, this reformulated infinite conjunction can be reformulated as a statement whose universal quantifier ranges over propositions:

> For all propositions p, if someone asserts that p, and p is false, then he or she is open to criticism

Or, to put it as some philosophers might:

> Truth is a norm of assertion.

For after all, if truth is a norm of assertion, then, if you assert something false, you are open to criticism. In short, then, deflationists are certainly not denying that truth is a norm of assertion; on the contrary, the concept of truth is required to state that very generalization.

If the problem of normativity is not the straightforward one that deflationists cannot account for the idea that truth is a norm of assertion, what is the problem? Crispin Wright argues that the problem is not so much that deflationists cannot account for normativity; rather, he suggests that the problem is twofold: first, that any theory of truth that *does* account for normativity is ipso facto not a *deflationary* theory properly so-called, and second, that any theory of truth which employs the equivalence schemas can account for normativity (Wright 1992; and see Price 1996 for discussion). The result is that, since most contemporary varieties of deflationism evidently employ the equivalence schemas, most contemporary varieties of deflationism are not varieties of deflationism properly so-called.

Wright's objection from normativity is a difficult one to assess. For one thing, it is difficult to find Wright's reason for supposing that the equivalence schemas play such a central role in the explanation of normativity. As we have seen, the equivalence schemas are crucial in providing a general statement of the

idea that truth is a norm of assertion, but there seems for all that no internal connection between truth and the norm in question, and thus no *internal* connection between the equivalence schemas and that norm (cf. Price 1996). Nor is it clear what role normativity plays in the distinction between an inflationary and a deflationary theory of truth. Certainly it is not good enough to simply *define* deflationism so that any deflationary theory cannot account for normativity. Of course, it is a consequence of a definition of this sort that a theory of truth is either inflationary or false; but then again, no deflationist will accept the definition.

Whatever one thinks of the details of Wright's objection, however, it does have far-reaching consequences for deflationism about truth. What the objection forces us to consider is the possibility that there is no very clear distinction between an inflationary and a deflationary theory of truth. Indeed, this possibility-that there is no clear inflationary/deflationary distinction-is the topic of the final objection to deflationism that I will discuss.

Objection #5: Inflationist Deflationism?

The final objection begins by drawing attention to a little known doctrine about truth that G.E.Moore held at the beginning of the century. Richard Cartwright describes the view as follows: "a true proposition is one that has a certain simple unanalyzable property, and a false proposition is one that lacks the property" (1987, p.73). This doctrine about truth is, of course, to be understood as the analogue for truth of the doctrine that Moore held about good, namely that good is a simple, unanalyzable quality.

The problem that this Moorean view about truth presents for the deflationary theory might best be expressed in the form of a question: what is the difference between the Moorean view and deflationism? Of course, there is a sense in which the flavour of the Moorean view is very different from the flavour of the deflationist theory about truth. After all, what could be more inflationary than thinking that truth is a property of a proposition that is unanalyzable? Certainly Moore's view about good has been viewed in this light. However, the fact that one view has a different flavour from another does not mean that, at bottom, they are not the same view. One might perhaps suggest that, according to the deflationary theory, the concept of truth has an important logical role, i.e., to capture generalizations. However, this doesn't really answer our question. For one thing, it isn't clear that Moore's notion might not also capture generalizations. For another, the idea that the deflationary concept of truth plays an important logical role doesn't distinguish the metaphysics of deflationism from the metaphysics of the Moorean view; and it is the metaphysics of the matter that the present objection really brings into focus. Alternatively, one might suggest that the distinction between truth according to deflationism and truth according to Moore's view is the distinction between having a simple unanalyzable nature, and not having a nature at all. However, what is that distinction? It is certainly not obvious that there is any distinction between having a nature about which nothing can be said and having no nature at all.

The problem is particularly acute in light of the fact that deflationism has often been discussed in the context of various claims about reductionism. In many discussions of deflationism, for example, the opponent is assumed to be a particular version of a correspondence theory that attempts to reduce the

correspondence relation to certain relations of causation (Field 1986 is a good example). However, it should be noted that this kind of view is also opposed to the kind of position that takes semantic facts-such as a proposition's being true-as primitive (Field 1972 is a good example). And the problem that we are considering for deflationism is that these two views are not simply identical in being opposed to the kind of view that explains correspondence in terms of causation: it is that they are identical *simpliciter*. The suggestion, in short, is that deflationism is identical to what initally seems to be its complete opposite, Moorean inflationism.

The decision to be an inflationist or a deflationist about truth has been called "the biggest decision a theorist of truth must make" (Boghossian 1990). Certainly this is true at an intuitive level. But it is sobering also to realize that it is not exactly clear what this decision amounts to when subjected to philosophical scrutiny. And this suggests that there is still a lot of work to be done before we can arrive at a final evaluation of the deflationary theory of truth.

The Correspondence Theory of Truth

Narrowly speaking, the correspondence theory of truth is the view that truth is correspondence to a fact -- a view that was advocated by Russell and Moore early in the 20th century. But the label is usually applied much more broadly to any view explicitly embracing the idea that truth consists in a relation to reality, i.e., that truth is a relational property involving a characteristic relation (to be specified) to some portion of reality (to be specified). During the last 2300 years this basic idea has been expressed in many ways, resulting in a rather extended family of views, theories, and theory sketches. The members of the family employ various concepts for the relevant relation (correspondence, conformity, congruence, agreement, accordance, copying, picturing, signification, representation, reference, satisfaction) and/or various concepts for the relevant portion of reality (facts, states of affairs, situations, events, objects, sequences of objects, sets, properties, tropes). The resulting multiplicity of versions and reformulations of the theory is due to a blend of substantive and terminological differences.

The correspondence theory of truth is often associated with metaphysical realism. Its traditional competitors, coherentist, pragmatist, and verificationist theories of truth, are often associated with idealism, anti-realism, or relativism. In recent years, the traditional competitors have been virtually replaced (at least from publication-space) by deflationary theories of truth -- and to a lesser extent by the identity theory -- which now lead the attack against correspondence theories.

---

1. History of the Correspondence Theory

The correspondence theory is often traced back to Aristotle's well-known definition of truth (*Metaphysics* 1011b25): “To say of what is that it is not, or of what is not that it is, is false, while to say of what is that it is, or of what is not that it is not, is true” -- but virtually identical formulations can be found in Plato (*Cratylus* 385b2, *Sophist* 263b). It is noteworthy that this definition does not highlight the basic correspondence intuition. Although it does invoke a relation (saying something *of* something) to reality (what is), the relation is not made very explicit, and there is no specification of what on the part of reality is responsible for the truth of a saying. The definition offers a muted, relatively minimal version of a correspondence theory. (For this reason it has also been interpreted as an impure precursor of deflationary theories of truth.) Aristotle sounds much more like a genuine correspondence theorist in the *Categories* (12b5, 14b15), where he talks of “underlying things” that make statements true and implies that these “things” (*pragmata*) are logically structured situations or facts (viz., his sitting, his not sitting). Most influential is his claim in *De Interpretatione* (16a3) that thoughts are “likenessess” (*homoiosis*) of things. Although he nowhere defines truth in terms of a thought's likeness to a thing or fact, it is clear that such a definition would fit well into his overall philosophy of mind.

In medieval authors we find a division between “metaphysical” and “semantic” versions of the correspondence theory. The former are indebted to the truth-as-likeness theme suggested by Aristotle's overall views, the latter are modeled on Aristotle's definition.

The best known is the metaphysical version presented by Thomas Aquinas: “*Veritas est adaequatio rei et intellectus*” -- truth is the equation of thing and intellect -- which he restates as: “A judgment is said to be true when it conforms to the external reality” (*De Veritate* Q.1, A.1&3; cf. *Summa Theologiae* Q.16). Aquinas credits the Neoplatonist Isaac Israeli with this definition. But there is no such definition in Isaac. It originated with the Arabic philosophers Avicenna and Averroes (*Tahafut*, 103, 302), and was introduced to the scholastics by William of Auxerre (cf. Boehner 1958; Wolenski 1994). The formula “equation of thing and intellect” is intended to leave room for the idea that “true” can be applied not only to thoughts and judgments but also to things (e.g. a true friend). Aquinas explains that a thought is said to be true because it conforms to reality, whereas a thing is said to be true because it conforms to a thought (a friend is true insofar as, and because, he conforms to our, or God's, conception of what a friend ought to be). This notion of thing-truth, which played an important role in ancient and medieval thinking, is disregarded by modern and analytic philosophers but survives to some extent in existentialist and continental philosophy.

Medieval authors who prefer a semantic version of the correspondence theory often use a peculiarly

truncated formula to render Aristotle's definition: A (mental) sentence is true iff, as it signifies, so it is (*sicut significat*, *ita est*). This emphasizes the semantic relation of signification while remaining maximally elusive about what it is that is signified by a true sentence. Foreshadowing a favorite approach of the 20th century, medieval semanticists like Ockham (*Summa Logicae II*) and Buridan (*Sophismata*) give exhaustive lists of different truth-conditional clauses for sentences of different grammatical categories; they systematically refrain from associating true sentences in general with a single ontological category.

Authors of the modern period generally convey the impression that the correspondence theory of truth is far too obvious to merit much, or any, discussion. Brief statements of some version or other can be found in almost all major writers; see e.g. Descartes 1639, ATII 597; Spinoza, *Ethics*, axiom vi; Locke, *Essay*, IV.v.i; Leibniz, *New Essays*, IV.v.ii; Hume, *Treatise*, 3.1.1; and Kant 1787, B82 -- Berkeley, who does not seem to offer any account of truth, is a potentially significant exception. Due to the influence of Thomism, metaphysical versions of the theory are more popular with the moderns than semantic versions. But since the moderns generally subscribe to a representational theory of the mind (the theory of ideas), they would seem to be committed to spelling out concepts like correspondence or conformity in terms of a psycho-semantic representation relation holding between ideas, or sequences of ideas, and appropriate portions of reality.

The now classical formulation of the theory appears in Moore (1910-11, chap. 15) and Russell: “Thus a belief is true when there is a corresponding fact, and is false when there is no corresponding fact” (1912, 129; cf. also his 1906). The self-conscious emphasis on facts as the corresponding portions of reality -- and a more serious concern with falsehood -- distinguishes this version from its precursors. Russell and Moore's forceful advocacy of truth as correspondence to fact was, at that time, an integral part of their defense of metaphysical realism. Their formulation is indebted to one of their idealist opponents, H. H. Joachim (1906), an early advocate of the coherence theory, who had set up a slightly more involved correspondence-to-fact account of truth as the main target of his attack on realism. Later, Wittgenstein (1921) and Russell (1918) developed “logical atomism”, which introduces an important modification of the correspondence approach. Further modification, and a return to more overtly semantic versions of the approach, was influenced by Tarski's (1935) technical work on truth (cf. Field 1972, Popper 1972).

2. Truth and Truthbearers

Correspondence theories of truth have been given for beliefs, thoughts, ideas, judgments, statements, assertions, utterances, sentences, and propositions. It has become customary to talk of “truthbearers” whenever one wants to stay neutral between these choices. Two points should be kept in mind: (i) The term is somewhat misleading; it is intended to refer to bearers of truth or falsehood (or alternatively, to things of which it makes sense to ask whether they are true or false, thus allowing for the possibility that some of them might be neither); (ii) One distinguishes between secondary and primary truthbearers. Secondary truthbearers are those whose truth-values (truth or falsehood) are derived from the truth-values of primary truthbearers, whose truth-values are not derived from any other truthbearers. It is often unproblematic to advocate one theory of truth for bearers of one type and another theory for bearers of a

different type (e.g., an identity theory of truth for propositions could be a component of a correspondence theory of truth for sentences): different theories applied to bearers of different types do not automatically compete. The standard segregation of truth theories into competing camps proceeds under the assumption, or pretense, that they are intended for primary truthbearers. Confusingly, there is little agreement as to which entities are properly taken to be primary truthbearers. Nowadays, the main contenders are public language sentences, sentences of the language of thought (mental representations), and propositions.

3. Simple Versions of the Correspondence Theory

Two simple forms of correspondence definitions of truth should be distinguished ("*x*" refers to whatever truthbearers might be taken as primary; the notion of correspondence might be replaced by various related notions):

> (1) *x* is true iff *x* corresponds to some fact;
> *x* is false iff *x* does not correspond to any fact;
>
> (2) *x* is true iff *x* corresponds to some state of affairs that obtains;
> *x* is false iff *x* corresponds to some state of affairs that does not obtain.

Both forms invoke portions of reality -- facts/states of affairs -- that are denoted by that-clauses or by sentential gerundives, viz., the fact/state of affairs *that snow is white*, or the fact/state of affairs of *snow's being white*. (2) is committed to the existence of non-obtaining entities of this sort; (1) is not, for to say that a fact does not obtain means, at best, that there is no such fact. It should be noted that this terminology is not standardized: some authors use "state of affairs" much like "fact" is used here (e.g. Armstrong 1997). The question whether non-obtaining entities of the relevant sort are to be accepted is the substantive issue behind such terminological variations. The difference between (2) and (1) is akin to the difference between Platonism about properties (embraces uninstantiated properties) and Aristotelianism (rejects uninstantiated properties).

Advocates of (2) typically hold that facts are states of affairs that obtain, i.e., they hold that their account of truth is in effect an analysis of (1)'s account of truth. So disagreement turns largely on the treatment of falsehood, which (1) simply identifies with the absence of truth.

The following points can be made for preferring (2) over (1): (a) Form (2) does not imply that things outside the category of truthbearers are false just because they don't correspond to facts. (b) Form (2) allows for items within the category of truthbearers that are neither true nor false, i.e., it allows for the failure of bivalence. (c) If the primary truthbearers are sentences or mental states, then states of affairs can be their meanings or contents, and the correspondence relation in (2) can be understood, accordingly, as the relation of representation, signification, meaning, or having-as-content. Facts, on the other hand, cannot be identified with the meanings or contents of sentences or mental states, on pain of the absurd consequence that false sentences and beliefs have no meaning or content. (d) Take a truth of the form '*p*

or *q*', where '*p*' is true and '*q*' false. What are the constituents of the corresponding fact? Since '*q*' is false, they cannot both be facts. (2) allows that the corresponding fact is a disjunctive state of affairs composed of a state of affairs that obtains and a state of affairs that does not obtain.

The main point in favor of (1) over (2) is that (1) is not committed to counting non-obtaining states of affairs, like the state of affairs that snow is green, as constituents of reality.

Both forms (1) and (2) should be distinguished from

> (3) *x* is true iff *x* corresponds to some fact that exists;
> *x* is false iff *x* corresponds to some fact that does not exist,

which is a confused version of (1), or a confused version of (2), or, if unconfused, implies commitment to Meinongianism, i.e., the thesis that there are things that do not exist. The lure of (3) stems from the desire to give a good account of falsehood while avoiding commitment to non-obtaining states of affairs. Moore sometimes succumbs to (3)'s temptations (1910-11, 269). It can also be found in Wittgenstein (1921, 4.25), who uses "*Sachverhalt*" to refer to (atomic) facts. The problem of falsehood -- How can we think what is not the case? -- which is related to the problem of nonexistence -- How can we think of what does not exist? -- was brought out nicely in Plato's *Theaetetus* (188c-89).

4. Arguments for the Correspondence Theory

The main positive argument given by advocates of the correspondence theory of truth is its obviousness. Descartes: "I have never had any doubts about truth, because it seems a notion so transcendentally clear that nobody can be ignorant of it…the word 'truth', in the strict sense, denotes the conformity of thought with its object" (1639, AT II 597); Kant: "The nominal definition of truth, that it is the agreement of [a cognition] with its object, is assumed as granted" (1787, B82); *Oxford English Dictionary*: "Truth, n. Conformity with fact; agreement with reality". Since the (relatively recent) arrival of apparently competing theories, correspondence theorists have added negative arguments to their arsenal, defending their view against objections and attacking (sometimes ridiculing) competing views.

5. Objections to the Correspondence Theory

***Objection 1*:** Definitions like (1) or (2) are too broad; although they apply to truths from some domains of discourse, e.g., the domain of science, they fail for others, e.g., the domain of morality: there are no moral facts.

The objection recognizes moral truths, but rejects the idea that reality contains moral facts. Logic provides another example of a domain that has been "flagged" in this way: the logical positivists recognized logical truths but rejected logical facts.

There are four possible responses to objections of this sort: (a) Error theory, which says that all claims from the flagged domain are false; (b) Noncognitivism, which says that, despite appearances to the contrary, claims from the flagged domain are not truth-evaluable to begin with, they are commands or emotions disguised as truthbearers; (c) Reductionism, which says that truths from the flagged domain correspond to facts of a different domain regarded as unproblematic, e.g., moral truths correspond to social-behavioral facts, logical truths correspond to facts about linguistic conventions; (d) Standing firm, i.e., embracing facts of the flagged domain. The last option can be supported by the following observation. The objection in effect maintains that there are different brands of *truth* (not just different brands of truths) for the different domains. This makes it hard to explain why there are many obviously valid arguments combining premises from flagged and unflagged domains.

***Objection 2*:** Correspondence theories are too obvious; they are trivial, vacuous, engaging in mere platitudes. Locutions from the “corresponds to the facts”-family are used regularly in everyday language as idiomatic substitutes for “true”. Such common turns of phrase should not be taken to indicate commitment to a correspondence *theory* in any serious sense. Definitions like (1) or (2) merely condense some trivial idioms into handy formulas; they don't deserve the grand label “theory”: there is no theoretical weight behind them (cf. Woozley 1949, chap. 6; Blackburn 1984, chap. 7.1).

In response, one could point out: (a) Definitions like (1) or (2) are “mini-theories” -- mini-theories are quite common in philosophy, and it is not obvious that they are vacuous merely because they are modeled on common usage; (b) There are correspondence theories that go beyond these definitions; (c) The complaint implies that definitions like (1) or (2) are generally accepted and are, moreover, so shallow that they are compatible with any deeper theory of truth. This makes it difficult to explain why a considerable number of thinkers emphatically reject all correspondence formulations. Moreover, the suggestion that the correspondence of *S*s belief to a fact could be said to consist in, e.g., its coherence with *S*s belief system seems quite implausible, even on the most shallow understanding of “correspondence” and “fact”.

***Objection 3*:** Correspondence theories are too obscure.

Objections of this sort, which are the most common, protest that the central notions of a correspondence theory carry unacceptable commitments and/or cannot be accounted for in any respectable manner. They might be divided into objections primarily aimed at the correspondence relation, or its relatives, and objections primarily aimed at the notions of fact or state of affairs:

3.C1: The correspondence relation must be some sort of resemblance relation. But truthbearers don't resemble anything in the world except other truthbearers -- echoing Berkeley's “an idea can be like nothing but an idea”.

3.C2: The correspondence relation is very mysterious: it seems to reach into the most distant regions of space (faster than light?) and time (past and future). How could such a relation possibly be accounted for within a naturalistic framework? What physical relation could it possibly be?

3.F1: Given the great variety of complex truthbearers, a correspondence theory will be committed to all sorts of complex “funny facts” that are ontologically disreputable: negative, disjunctive, conditional, universal, probabilistic, subjunctive, and counterfactual facts have all given cause for complaint on this score.

3.F2:All facts, even the most simple ones, are disreputable. Fact-talk, being wedded to that-clauses, is entirely parasitic on truth-talk. Facts are too much like truthbearers. Facts are fictions, spurious sentence-like slices of reality, “projected from true sentences for the sake of correspondence” (Quine 1987, 213; cf. Strawson 1950).

6. Correspondence as Isomorphism

A correspondence theory is usually expected to go beyond a mere definition like (1) or (2) and discharge a triple task: it should tell us about the workings of the correspondence relation, about the nature of facts, and about the conditions that determine which truthbearers correspond to which facts. It is natural to tackle this by construing correspondence as an *isomorphism* between truthbearers and facts (cf. Kirkham 1992, chap. 4). The basic idea is that truthbearers and facts are both complex structured entities: truthbearers are composed of words, or concepts, and other truthbearers; facts are composed of things, properties, relations, and other facts or states of affairs. The aim is to show how the correspondence relation is generated from underlying relations between the ultimate constituents of truthbearers and the ultimate constituents of their corresponding facts. One part of the project will be concerned with these correspondence-generating relations: it will lead into a theory that addresses the question how simple words, or concepts, can be *about* things, properties, and relations; i.e., it will merge with semantics or psycho-semantics (depending on what the truthbearers are taken to be). The other part of the project, the specifically ontological part, will have to provide identity criteria for facts and explain how their simple constituents combine into complex wholes. Putting all this together should yield an account of the conditions determining which truthbearers correspond to which facts.

The isomorphism approach offers an answer to objection 3.C1. Although the truth that the cat is on the mat does not resemble the cat or the mat (the truth doesn't smell, etc.), it does resemble the fact that the cat is on the mat. This is not a qualitative resemblance; it is a more abstract, structural resemblance.

The approach also puts objection 3.C2 in some perspective. The correspondence relation is supposed to reduce to underlying relations between words, or concepts, and reality. Consequently, a correspondence theory is little more than a spin-off from semantics and/or psycho-semantics (the theory of intentionality). This reminds us that, as a relation, correspondence is no more -- but also no less -- mysterious than semantic relations in general. Such relations have some curious features, and they raise a host of puzzles and difficult questions -- most notoriously: Can they be explained in terms of natural (causal) relations, or do they have to be regarded as irreducibly non-natural aspects of reality? Some philosophers have claimed that semantic relations are too mysterious to be taken seriously, usually on the grounds that they are not explainable in naturalistic terms. But one should bear in mind that this is a very

general and extremely radical attack on semantics as a whole, on the very idea that words and concepts can be about things. The common practice to aim it specifically at the correspondence theory seems misleading. As far as the intelligibility of the correspondence relation is concerned, the correspondence theory will stand, or fall, with the general theory of reference and intentionality.

On a straightforward implementation of the isomorphism approach, correspondence will be a one-one relation between truths and corresponding facts, which leaves the approach vulnerable to objections against funny facts (3.F1): each true truthbearer, no matter how complex, will be assigned a matching fact. Moreover, since the approach assigns corresponding entities to all (relevant) constituents of truthbearers, complex facts will contain objects corresponding to the logical constants ("not", "or", "if-then", etc.), and these "logical objects" will have to be regarded as constituents of the world. Many philosophers have found it hard to believe in the existence of all these funny facts and objects.

The isomorphism approach has never been advocated in a fully naïve form, assigning corresponding objects to each and every wrinkle of our verbal or mental utterings. Instead, proponents try to isolate the "relevant" constituents of truthbearers through meaning analysis, aiming to uncover the logical form, or deep structure, behind ordinary language and thought. This deep structure might then be expressed in an "ideal-language" (e.g., the language of predicate logic) whose syntactic structure is designed to mirror perfectly the ontological structure of reality. The resulting view -- correspondence as isomorphism between properly analyzed truthbearers and facts -- avoids assigning strange objects to such phrases as "the average husband", "the present king of France", or "the sake of", the view remains committed to logically complex facts and to logical objects corresponding to the logical constants.

Austin (1950) rejects the isomorphism approach on the grounds that it reads the structure of our language into the world. On his version of the correspondence theory (a more elaborated variant of (2) applied to statements), a statement as a whole is correlated to a state of affairs by arbitrary linguistic conventions without mirroring the inner structure of its correlate. This approach appears vulnerable to the objection that it avoids funny facts at the price of neglecting systematicity. Language does not provide separate linguistic conventions for each statement: that would require too vast a number of conventions. Rather, it seems that the truth-values of statements are systematically determined, via a relatively small set of conventions, by the semantic values (relations to reality) of their simpler constituents. Recognition of this systematicity is built right into the isomorphism approach.

7. Modified Versions of the Correspondence Theory

7.1 *Logical Atomism*

Wittgenstein (1921) and Russell (1918) propose a modified correspondence account of truth as part of their program of "logical atomism". Such an account proceeds in two stages: (A) the basic truth-definition, say (1), is restricted to a special subclass of truthbearers, the so-called elementary, or atomic, truthbearers; (B) the truth-values of non-elementary, or molecular, truthbearers are explained *recursively*

in terms of their logical structure and the truth-values of their simpler constituents: for example, a sentence of the form ‘not-*p*’ is true iff ‘*p*’ is false; a sentence of the form ‘*p* and *q*’ is true iff ‘*p*’ is true and ‘*q*’ is true; a sentence of the form ‘*p* or *q*’ is true iff ‘*p*’ is true or ‘*q*’ is true, etc. These recursive clauses (called “truth conditions”) can be reapplied until the truth of a molecular sentence of arbitrary complexity is reduced to the truth or falsehood of its atomic constituents. Definition (1), restricted to atomic truthbearers, serves as the base-clause for the truth-conditional recursions.

Such an account of truth is designed to go with the ontological view that the world is the totality of atomic facts (cf. Wittgenstein 1921, 2.04); i.e., atomic facts are all the facts there are -- although logical atomists tend to allow conjunctive facts, regarding them as mere aggregates of atomic facts. An atomic truth is true because it corresponds to an atomic fact: correspondence is still isomorphism, but it holds exclusively between atomic truths and atomic facts. Molecular truths are not assigned any matching facts: strictly speaking, they do not correspond to facts at all; but their truth-values are explained in terms of logical structure and correspondence of atomic constituents. One-one correspondence is restricted to the atomic level; above that level, there is no one-one correlation between truths and facts (e.g., ‘*p*’, ‘*p* or *q*’, and ‘*p* or *r*’ might all be true merely because ‘*p*’ corresponds to a fact). The trick for avoiding logically complex facts lies in not assigning any entities to the logical constants. Logical complexity, so the idea goes, belongs to the structure of language and/or thought; it is not a feature of the world.

While Wittgenstein and Russell seem to have held that the constituents of atomic facts are to be determined on the basis of *a priori* considerations, Armstrong (1997) advocates an *a posteriori* form of logical atomism. On his view, atomic facts are composed of particulars and simple universals (properties and relations). The latter are objective features of the world that ground the objective resemblances between particulars and explain their causal powers. Accordingly, what particulars and universals there are will have to be determined on the basis of total science.

Logical atomism is not easy to sustain and has rarely been held in a pure form. Among its difficulties are the following: (a) There are molecular truthbearers, like subjunctives and counterfactuals, that tend to provoke the funny-fact objection but cannot be handled by simple truth-conditional clauses because their truth-values do not seem to be determined by the truth-values of their atomic constituents. (b) Are there universal facts corresponding to true universal generalizations? Wittgenstein (1921) disapproves of universal facts; apparently, he wants to reanalyze universal generalizations as infinite conjunctions of their instances. Russell (1918) and Armstrong (1997) reject this analysis; they admit universal facts. (c) Negative truths are the most notorious problem case, because they clash with an appealing principle, the “truthmaker principle” (Armstrong 1997, chap. 8), which says that for every truth there must be something in the world that makes it true, i.e., every true truthbearer must have a truthmaker. On the account given above, ‘not-*p*’ is true iff ‘*p*’ is false iff ‘*p*’ does not correspond to any fact; hence, ‘not-*p*’ is not made true by any fact: it does not seem to have a truthmaker. Russell finds himself driven to admit negative facts, regarded by many as paradigmatically disreputable portions of reality. Wittgenstein (cf. 1921, 2.06) sometimes talks of atomic facts that do not exist and calls their very nonexistence a negative fact -- but this is hardly an atomic fact itself. Armstrong (1997, chap. 8.7) holds that negative truths are made true by a second-order “totality fact” which says of all the (positive) first-order facts that they are all the first-order facts.

Logical atomism is designed to address objections to funny facts (3.F1). It is not designed to address objections to facts in general (3.F2). Here logical atomists will respond by defending (atomic) facts. According to one defense, facts are needed because mere objects are not sufficiently *articulated* to serve as truthmakers. If *a* were the sole truthmaker of ‘*a* is *F*’, then the latter should imply ‘*a* is *G*’, for any ‘*G*’. So the truthmaker for ‘*a* is *F*’ needs at least to involve *a* and *F*ness. But since *F*ness is a universal, it could be instantiated in another object, *b*, hence the mere existence of *a* and *F*ness is not sufficient for making true the claim ‘*a* is *F*’: *a* and *F*ness need to be tied together in the fact of *a*'s being *F*. Armstrong (1997) and Olson (1987) also maintain that facts are needed to make sense of the tie that binds particular objects to universals. In this context it is usually emphasized that facts do not supervene on, hence, are not reducible to, their constituents. Facts are entities *over and above* the particulars and universals of which they are composed: *a*'s loving *b* and *b*'s loving *a* are not the same fact even though they have the same constituents. Another defense, surprisingly rare, would point out that many facts are observable: one can see that the cat is on the mat; and this is different from seeing the cat, or the mat, or both -- the objection that many facts are not observable invites the rejoinder that many objects are not observable either.

Some logical atomists propose a version of (1) without facts because they regard facts as too sentence-like. Instead, they propose events and/or objects-plus-tropes as the corresponding portions of reality. It is claimed that these items are more “thingy” than facts but still sufficiently articulated -- and sufficiently abundant -- to serve as adequate truthmakers (cf., e.g., Mulligan, Simons, and Smith 1984).

7.2 *Logical “Subatomism”*

Logical atomism aims at getting by without complex truthmakers by restricting definitions like (1) or (2) to atomic truthbearers and accounting for the truth-values of molecular truthbearers recursively in terms of their logical structure and atomic truthmakers (atomic facts, events, objects-plus-tropes). More radical modifications of the correspondence theory push the recursive strategy even further, entirely discarding definitions like (1) or (2), and hence the need for atomic truthmakers, by going, as it were, “*subatomic*”.

Such accounts analyze truthbearers, e.g., sentences, into their subsentential constituents and dissolve the relation of correspondence into appropriate semantic subrelations: names *refer* to, or denote, objects; predicates (open sentences) apply to objects, or are *satisfied* by objects. Satisfaction of complex predicates can be handled recursively in terms of logical structure and satisfaction of simpler constituent predicates: an object *o* satisfies ‘*x* is not *F*’ iff *o* does not satisfy ‘*x* is *F*’; *o* satisfies ‘*x* is *F* or *x* is *G*’ iff *o* satisfies ‘*x* is *F*’ or *o* satisfies ‘*x* is *G*’; and so on. These recursions are anchored in a base-clause addressing the satisfaction of *primitive* predicates: e.g., *o* satisfies ‘*x* is *F*’ iff *o* instantiates the property expressed by ‘*F*’ -- some would prefer a more nominalistic base-clause for satisfaction, hoping to get by without seriously invoking properties. Truth for singular sentences, consisting of a name and an arbitrarily complex predicate, is defined thus: A singular sentence is true iff the object denoted by the name satisfies the predicate. Logical machinery provided by Tarski (1935) can be used to turn this simplified sketch into a more general definition of truth -- a definition that handles sentences containing

relational predicates and quantifiers and covers molecular sentences as well. (Whether Tarski's own definition of truth can be regarded as a correspondence definition even in this modified sense is under debate; cf. Popper 1972; Field 1972, 1986; Kirkham 1992, chaps. 5-6; Soames 1999.)

Since it promises to avoid facts and all similarly articulated, sentence-like slices of reality, correspondence theorists who take seriously objection 3.F2 favor this subatomistic approach: not even atomic truthbearers are assigned any matching truthmakers. The correspondence relation itself has given way to two semantic relations between constituents of truthbearers and objects: denotation and satisfaction -- relations central to any semantic theory. Some advocates envision causal accounts of denotation and satisfaction (cf., Field 1972; Devitt 1982, 1984; Schmitt 1995; Kirkham 1992, chaps. 5-6). It turns out that relational predicates require talk of satisfaction by ordered *sequences* of objects. Davidson (1969, 1977) maintains that satisfaction by sequences is all that remains of the traditional idea of correspondence to facts; he regards denotation and satisfaction as "theoretical constructs" not in need of causal, or any, explanation.

Problems: (a) The subatomistic approach accounts for the truth-values of molecular truthbearers in the same way as the atomistic approach; consequently, molecular truthbearers that are not truth-functional pose similar problems. (b) Belief attributions and modal claims pose special problems; e.g., it seems that "believes" is a relational predicate, so that "John believes that snow is white" is true iff "believes" is satisfied by John and the object denoted by "that snow is white"; but the latter appears to be a proposition or state of affairs, which threatens to let in through the back-door the very sentence-like slices of reality the subatomic approach was supposed to avoid; (c) The phenomenon of referential indeterminacy threatens to undermine the idea that the truth-values of atomic truthbearers are always determined by the denotation and/or satisfaction of their constituents; e.g., pre-relativistic uses of the term "mass" are plausibly taken to lack determinate reference (referring determinately neither to relativistic mass nor to rest mass); yet a claim like "The mass of the earth is greater than the mass of the moon" seems to be determinately true even when made by Newton (cf. Field 1973).

Problems for both versions of modified correspondence theories: (a) It is not known whether an entirely general recursive definition of truth, one that covers all truthbearers, can be made available. This depends on unresolved issues concerning the extent to which truthbearers are amenable to the kind of structural analyses that are presupposed by the recursive clauses. The more an account of truth wants to exploit the internal structure of truthbearers, the more it will be hostage to the (limited) availability of appropriate structural analyses of the relevant truthbearers. (b) Any account of truth that employs recursions may be virtually committed to taking sentences (maybe sentences of the language of thought) as primary truthbearers. After all, the recursive clauses rely heavily on what appears to be the logico-syntactic structure of truthbearers, and it is unclear whether anything but sentences can plausibly be said to possess this kind of structure. The thesis that sentences of any sort can be regarded as primary truthbearers is contentious. (c) If clauses like "'*p* or *q*' is true iff '*p*' is true or '*q*' is true" are to be used in a recursive account of *our* notion of *truth*, as opposed to some other notion, it has to be presupposed that 'or' expresses *disjunction*: one cannot define 'or' and 'true' at the same time. To avoid circularity, a modified correspondence theory (be it atomic or subatomic) must hold that the logical connectives can be understood without reference to correspondence truth.

8. The Correspondence Theory and Its Competitors

A. Against the traditional competitors -- coherentist, pragmatist, and verificationist and other epistemic theories of truth -- correspondence theorists raise two main sorts of objections. First, these competing accounts tend to lead into relativism. Take, e.g., a coherentist account of truth. Since it is possible that '*p*' coheres with the belief system of *S* while 'not-*p*' coheres with the belief system of *S**, the coherentist account seems to imply, absurdly, that contradictories, '*p*' and 'not-*p*', could both be true. To avoid embracing contradictions, coherentists often commit themselves (if only covertly) to the objectionable relativistic view that '*p*' is true-for-*S* and 'not-*p*' is true-for-*S**. Second, the competing accounts tend to lead into some form of idealism or anti-realism. E.g., it is possible for the belief that *p* to cohere with someone's belief system even though it is not a fact that *p*; also, it is possible for it to be a fact that *p* even though no one believes that *p*, or the belief that *p* does not cohere with anyone's belief system. Cases of this form are frequently cited as counterexamples to coherentist accounts of truth. Coherentists tend to reject such counterexamples by insisting that they are not possible after all -- a reaction that commits them to the anti-realist view that the facts are (largely) determined by what we believe.

B. According to the identity theory of truth, true propositions do not correspond to facts, they are (identical with) facts: the true proposition that snow is white = the fact that snow is white. This non-traditional competitor of the correspondence theory threatens to collapse the correspondence relation into identity. In response, a correspondence theorist might point out: First, the identity theory is defensible only for propositions as truthbearers, and only if propositions are construed in a certain way, namely as having objects and properties as constituents rather than ideas or concepts of objects and properties. Hence, even if the identity theory of truth were accepted for propositions (so construed), there would still be ample room (and need) for correspondence accounts of truth with respect to other types of truthbearers. Second, the identity theory rests on the assumption that that-clauses always denote propositions, so that the that-clause in "the fact that snow is white" denotes the proposition that snow is white. The assumption can be questioned. That-clauses can be understood as ambiguous names, sometimes denoting propositions and sometimes denoting facts. The descriptive phrases "the proposition…" and "the fact…" can be regarded as serving to disambiguate the succeeding ambiguous that-clauses -- much like the descriptive phrases in "the philosopher Socrates" and "the soccer-player Socrates" serve to disambiguate the ambiguous name "Socrates" (cf. David 2002).

C. At present the most noticeable competitors to correspondence theories are deflationary accounts of truth. Deflationists maintain that correspondence theories need to be deflated. Their central notions, correspondence and fact (and their relatives), are said to play no legitimate role in an adequate account of truth: they can be excised without loss. A correspondence-type formulation like

> (4) "Snow is white" is true iff it corresponds to the fact that snow is white,

is to be deflated to

(5) “Snow is white” is true iff snow is white,

which, according to deflationists, says all there is to be said about the truth of “Snow is white” without superfluous embellishments (cf. Quine 1987, 213).

Correspondence theorists protest that (5) cannot lead to anything deserving to be regarded as an account or theory of truth because it resists generalization. (5) is a substitution instance of the schema

(6) “*p*” is true iff *p*,

which does not say anything itself and cannot be turned into a genuine generalization about truth; moreover, no genuine generalizations about truth can be accounted for on the basis of (6). Correspondence definitions, on the other hand, i.e., definitions like (1) or (2), do yield genuine generalizations about truth. (It should be noted that (4), which lends itself to deflating excisions, misrepresents the correspondence theory. According to (4), corresponding to the fact that snow is white is sufficient and necessary for “Snow is white” to be true. Yet, according to (1) and (2), it is sufficient but not necessary: “Snow is white” will be true as long as it corresponds to some fact or other. The genuine article, (1) or (2), is not as easily deflated as (4).)

This debate turns crucially on the question whether anything deserving to be called an “account” or “theory” of truth ought to take the form of a genuine generalization (and ought to be able to account for genuine generalizations involving truth). Correspondence theorists tend to regard this as a (minimal) requirement. Deflationists argue that truth is a shallow (sometimes “logical”) notion -- a notion that has no serious explanatory role to play: as such it does not require a full-fledged account, a real theory, that would have to take the form of a genuine generalization (cf. Devitt 1984; Field 1986; Kirkham 1992; Gupta 1993; David 1994; Schmitt 1995; and the essays in Blackburn and Simmons 1999, and in Schantz 2002).

9. More Objections to the Correspondence Theory

Two final objections to the correspondence theory should be mentioned.

9.1 *The Big Fact*

Inspired by a similar argument of Frege's, Davidson (1969) argues that the correspondence theory is bankrupt because it cannot avoid the consequence that all true sentences correspond to the same fact: the Big Fact.

Assume that a given sentence, *s*, corresponds to the fact that *p*; assume furthermore that ‘*p*’ and ‘*q*’ have the same truth-value. Now, since

p

implies

$\{x: x = x \;\&\; p\} = \{x: x = x\}$,

which implies

$\{x: x = x \;\&\; q\} = \{x: x = x\}$,

which in turn implies

q,

it follows that

s corresponds to the fact that *p*

implies

s corresponds to the fact that *q*.

Since the only restriction on ‘*q*’ was that it has the same truth-value as ‘*p*’, it would follow that any sentence that corresponds to any fact corresponds to every fact, so that all true sentences correspond to the same facts, thereby proving the emptiness of the correspondence theory -- the conclusion of the argument is taken as tantamount to the conclusion that every true sentence corresponds to the totality of all the facts, i.e, the Big Fact, i.e., the world as a whole.

This argument, which is a variation on the so-called “slingshot argument”, has been criticized repeatedly. Critics point out that it relies on two assumptions: (i) logically equivalent sentences can be substituted in the context “corresponds to the fact that…”; and (ii) if definite descriptions denoting the same thing can be substituted for each other in a given sentence, then they can still be so substituted if that sentence is embedded within the context “corresponds to the fact that…” (in the version above the relevant descriptions are “$\{x: x = x \;\&\; p\}$” and “$\{x: x = x \;\&\; q\}$”). It is far from obvious why correspondence theorists should be tempted by either one of these assumptions (cf. Olson 1987).

9.2 *No Independent Access*

The objection that may well have been the most effective in causing discontent with the correspondence theory is based on an epistemological concern. In a nutshell, the objection is that a correspondence theory of truth must inevitably lead into skepticism about the external world because the required correspondence between our thoughts and reality is not ascertainable. Ever since Berkeley's attack on the representational theory of the mind, objections of this sort have enjoyed considerable popularity. It is typically pointed out that we cannot step outside our own minds to compare our thoughts with mind-independent reality. Yet -- so the objection continues -- on the correspondence theory of truth, this is precisely what we would have to do to gain knowledge. We would have to access reality as it is in itself, independently of our cognition of it, and determine whether our thoughts correspond to it. Since this is impossible, since all our access to the world is mediated by our cognition, the correspondence theory makes knowledge impossible. Assuming that the resulting skepticism is unacceptable, the correspondence theory has to be rejected. This type of objection brings up a host of issues in epistemology, the philosophy of mind, and general metaphysics. All that can be done here is to hint at a few pertinent points.

The objection makes use of the following line of reasoning: “If truth is correspondence, then, since knowledge requires truth, we have to know that our beliefs correspond to reality, if we are to know anything about reality”. There are two assumptions implicit in this line of reasoning; both of them debatable. (i) It is assumed that *S* knows *x* only if *S* knows that *x* is true -- a requirement not underwritten by standard definitions of knowledge, which tell us that *S* knows *x* only if *x* is true and *S* is justified in believing *x*. The assumption may rest on confusing requirements for knowing *x* with requirements for knowing that one knows *x*. (ii) It is assumed that, if truth = *F*, then *S* knows that *x* is true only if *S* knows that *x* has *F*. This seems highly implausible. By the same standard it would follow that no one who does not know that water is H_2O can know that the Nile contains water -- which would mean, of course, that until fairly recently nobody knew that the Nile contained water (that there were stars in the sky, whales in the sea, or that the sun gives light). Moreover, even if one does know that Water is H_2O, one's strategy for finding out whether the liquid in one's glass is water does not have to involve chemical analysis. Similarly, it seems the correspondence theory does not entail that we have to know that a belief corresponds to a fact in order to know that it is true, or that our method of finding out whether a belief is true has to involve a strategy of actually comparing a belief with a fact -- although the theory does of course entail that obtaining knowledge amounts to obtaining a belief that corresponds to a fact.

More generally, one might question whether the objection still has much bite once the metaphors of “accessing” and “comparing” are spelled out with more attention to the psychological details involved in belief formation and the epistemological issues involved in the question under what conditions a belief is justified or warranted. Finally, one might wonder whether competing accounts of truth actually enjoy any significant advantage over the correspondence theory when held to the standards set up by this sort of objection.

The Coherence Theory of Truth

A coherence theory of truth states that the truth of any (true) proposition consists in its coherence with some specified set of propositions. The coherence theory differs from its principal competitor, the correspondence theory of truth, in two essential respects. The competing theories give conflicting accounts of the relation between propositions and their truth conditions. (In this article, 'proposition' is not used in any technical sense. It simply refers to the bearers of truth values, whatever they may be.) According to one, the relation is coherence, according to the other, it is correspondence. The two theories also give conflicting accounts of truth conditions. According to the coherence theory, the truth conditions of propositions consist in other propositions. The correspondence theory, in contrast, states that the truth conditions of propositions are not (in general) propositions, but rather objective features of the world. (Even the correspondence theorist holds that propositions about propositions have propositions as their truth conditions.)

Versions of the Coherence Theory of Truth

The coherence theory of truth has several versions. These versions differ on two major issues. Different versions of the theory give different accounts of the coherence relation. Different varieties of the theory also give various accounts of the set (or sets) of propositions with which true propositions cohere. (I will refer to such a set as a *specified set*.)

According to some early versions of the coherence theory, the coherence relation is simply consistency. On this view, to say that a proposition coheres with a specified set of propositions is to say that the proposition is consistent with the set. This account of coherence is unsatisfactory for the following reason. Consider two propositions which do not belong to a specified set. These propositions could both

be consistent with a specified set and yet be inconsistent with each other. If coherence is consistency, the coherence theorist would have to claim that both propositions are true, but this is impossible.

A more plausible version of the coherence theory states that the coherence relation is some form of entailment. Entailment can be understood here as strict logical entailment, or entailment in some looser sense. According to this version, a proposition coheres with a set of propositions if and only if it is entailed by members of the set.

The second point on which coherence theorists (coherentists, for short) differ is the constitution of the specified set of propositions. Coherentists generally agree that the specified set consists of propositions believed or held to be true. They differ on the questions of who believes the propositions and when. At one extreme, coherence theorists can hold that the specified set of propositions is the largest consistent set of propositions currently believed by actual people. For such a version of the theory, see Young (1995). According to a moderate position, the specified set consists of those propositions which will be believed when people like us (with finite cognitive capacities) have reached some limit of inquiry. For such a coherence theory, see Putnam (1981). At the other extreme, coherence theorists can maintain that the specified set contains the propositions which would be believed by an omniscient being. Some idealists seem to accept this account of the specified set.

If the specified set is a set actually believed, or even a set which would be believed by people like us at some limit of inquiry, coherentism involves the rejection of realism about truth. Realism about truth involves acceptance of the principle of bivalence (according to which every proposition is either true or false) and the principle of transcendence (which says that a proposition may be true even though it cannot be known to be true). Coherentists who do not believe that the specified set is the set of propositions believed by an omniscient being are committed to rejection of the principle of bivalence since it is not the case that for every proposition either it or a contrary proposition coheres with the specified set. They reject the principle of transcendence since, if a proposition coheres with a set of beliefs, it can be known to cohere with the set.

Arguments for Coherence Theories of Truth

Two principal lines of argument have led philosophers to adopt a coherence theory of truth. Early advocates of coherence theories were persuaded by reflection on metaphysical questions. More recently, epistemological and semantic considerations have been the basis for coherence theories.

The Metaphysical Route to Coherentism

Early versions of the coherence theory were associated with idealism. Walker (1989) attributes coherentism to Spinoza, Kant, Fichte and Hegel. Certainly a coherence theory was adopted by a number of British Idealists in the last years of the nineteenth century and the first decades of the twentieth. See, for example, H.H. Joachim (1906).

Idealists are led to a coherence theory of truth by their metaphysical position. Advocates of the correspondence theory believe that a belief is (at least most of the time) ontologically distinct from the objective conditions which make the belief true. Idealists do not believe that there is an ontological distinction between beliefs and what makes beliefs true. From the idealists' perspective, reality is something like a collection of beliefs. Consequently, a belief cannot be true because it corresponds to something which is not a belief. Instead, the truth of a belief can only consist in its coherence with other beliefs. A coherence theory of truth which results from idealism usually leads to the view that truth comes in degrees. A belief is true to the degree that it coheres with other beliefs.

In recent years metaphysical arguments for coherentism have found few advocates. This is due to the fact that idealism is not widely held.

Epistemological Routes to Coherentism

Blanshard (1939, ch. XXVI) argues that a coherence theory of justification leads to a coherence theory of truth. His argument runs as follows. Someone might hold that coherence with a set of beliefs is the test of truth but that truth consists in correspondence to objective facts. If, however, truth consists in correspondence to objective facts, coherence with a set of beliefs will not be a test of truth. This is the case since there is no guarantee that a perfectly coherent set of beliefs matches objective reality. Since coherence with a set of beliefs is a test of truth, truth cannot consist in correspondence.

Blanshard's argument has been criticised by, for example, Rescher (1973). Blanshard's argument depends on the claim that coherence with a set of beliefs is the test of truth. Understood in one sense, this claim is plausible enough. Blanshard, however, has to understand this claim in a very strong sense: coherence with a set of beliefs is an infallible test of truth. If coherence with a set of beliefs is simply a good but fallible test of truth, as Rescher suggests, the argument fails. The "falling apart" of truth and justification to which Blanshard refers is to be expected if truth is only a fallible test of truth.

Another epistemological argument for coherentism is based on the view that we cannot "get outside" our set of beliefs and compare propositions to objective facts. A version of this argument was advanced by some logical positivists including Hempel (1935) and Neurath (1983). This argument, like Blanshard's, depends on a coherence theory of justification. The argument infers from such a theory that we can only know that a proposition coheres with a set of beliefs. We can never know that a proposition corresponds to reality.

This argument is subject to at least two criticisms. For a start, it depends on a coherence theory of justification, and is vulnerable to any objections to this theory. More importantly, a coherence theory of truth does not follow from the premisses. We cannot infer from the fact that a proposition cannot be known to correspond to reality that it does not correspond to reality. Even if correspondence theorists admit that we can only know which propositions cohere with our beliefs, they can still hold that truth consists in correspondence. If correspondence theorists adopt this position, they accept that there may be truths which cannot be known. Alternatively, they can argue, as does Davidson (1986), that the

coherence of a proposition with a set of beliefs is a good indication that the proposition corresponds to objective facts and that we can know that propositions correspond.

Coherence theorists need to argue that propositions cannot correspond to objective facts, not merely that they cannot be known to correspond. In order to do this, the foregoing argument for coherentism must be supplemented. One way to supplement the argument would be to argue as follows. As noted above, the correspondence and coherence theories have differing views about the nature of truth conditions. One way to decide which account of truth conditions is correct is to pay attention to the process by which propositions are assigned truth conditions. Coherence theorists can argue that the truth conditions of a proposition are the conditions under which speakers make a practice of asserting it. Coherentists can then maintain that speakers can only make a practice of asserting a proposition under conditions the speakers are able to recognise as justifying the proposition. Now the (supposed) inability of speakers to "get outside" of their beliefs is significant. Coherentists can argue that the only conditions speakers can recognise as justifying a proposition are the conditions under which it coheres with their beliefs. When the speakers make a practice of asserting the proposition under these conditions, they become the proposition's truth conditions. For an argument of this sort see Young (1995).

Criticisms of Coherence Theories of Truth

Any coherence theory of truth faces two principal challenges. The first may be called the specification objection. The second is the transcendence objection.

The Specification Objection

According to the specification objection, coherence theorists have no way to identify the specified set of propositions without contradicting their position. This objection originates in Russell (1907). Opponents of the coherence theory can argue as follows. The proposition (1) ‘Jane Austen was hanged for murder’ coheres with some set of propositions. (2) ‘Jane Austen died in her bed’ coheres with another set of propositions. No one supposes that the first of these propositions is true, in spite of the fact that it coheres with a set of propositions. The specification objection charges that coherence theorists have no grounds for saying that (1) is false and (2) true.

Some responses to the specification problem are unsuccessful. One could say that we have grounds for saying that (1) is false and (2) is true because the latter coheres with propositions which correspond to the facts. Coherentists cannot, however, adopt this response without contradicting their position. Sometimes coherence theorists maintain that the specified system is the most comprehensive system, but this is not the basis of a successful response to the specification problem. Coherentists can only, unless they are to compromise their position, define comprehensiveness in terms of the size of a system. Coherentists cannot, for example, talk about the most comprehensive system composed of propositions which correspond to reality. There is no reason, however, why there cannot be two or more equally large systems. Other criteria of the specified system, to which coherentists frequently appeal, are similarly unable to solve the specification problem. These criteria include simplicity, empirical adequacy and

others. Again, there seems to be no reason why two or more systems cannot equally meet these criteria.

Although some responses to the Russell's version of the specification objection are unsuccessful, it is unable to refute the coherence theory. Coherentists do not believe that the truth of a proposition consists in coherence with any arbitrarily chosen set of propositions. Rather, they hold that truth consists in coherence with a set of beliefs, or with a set of propositions held to be true. No one actually believes the set of propositions with which (1) coheres. Coherence theorists conclude that they can hold that (1) is false without contradicting themselves.

A more sophisticated version of the specification objection has recently been advanced by Walker (1989); for a discussion, see Wright (1995). Walker argues as follows. In responding to Russell's version of the specification objection, coherentists claim that some set of propositions, call it *S*, is believed. They are committed to the truth of (3) ‘*S* is believed.’ The question of what it is for (3) to be true then arises. Coherence theorists might answer this question by saying that "‘*S* is believed’ is believed" is true. If they give this answer, they are apparently off on an infinite regress, and they will never say what it is for a proposition to be true. Their plight is worsened by the fact that arbitrarily chosen sets of propositions can include propositions about what is believed. So, for example, there will be a set which contains ‘Jane Austen was hanged for murder,’ "‘Jane Austen was hanged for murder’ is believed," and so on. The only way to stop the regress seems to be to say that the truth conditions of (3) consist in the fact *S* is believed. If, however, coherence theorists adopt this position, they seem to contradict their own position by accepting that the truth conditions of some proposition consist in facts, not in propositions in a set of beliefs.

There is some doubt about whether Walker's version of the specification objection succeeds. Coherence theorists can reply to Walker by saying that nothing in their position is inconsistent with the view that there is a fact about which set of propositions is believed. Even though this fact obtains, however, the truth conditions of propositions, including propositions about which sets of propositions are believed, are the conditions under which they cohere with a set of propositions. For a defence of the coherence theory again Walker's version of the specification objection, see Young (2001).

A coherence theory of truth gives rise to a regress, but it is not a vicious regress and the correspondence theory faces a similar regress. If we say that *p* is true if and only if it coheres with a specified set of propositions, we may be asked about the truth conditions of ‘*p* coheres with a specified set.’ Plainly, this is the start of a regress, but not one to worry about. It is just what one would expect, given that the coherence theory states that it gives an account of the truth conditions of all propositions. The correspondence theory faces a similar benign regress. The correspondence theory states that a proposition is true if and only if it corresponds to certain objective conditions. The proposition ‘*p* corresponds to certain objective conditions’ is also true if and only if it corresponds to certain objective conditions, and so on.

The Transcendence Objection

The transcendence objection charges that a coherence theory of truth is unable to account for the fact that some propositions are true which cohere with no set of beliefs. According to this objection, truth transcends any set of beliefs. Someone might argue, for example, that the proposition ‘Jane Austen wrote ten sentences on November 17th, 1807’ is either true or false. If it is false, some other proposition about how many sentences Austen wrote that day is true. No proposition, however, about precisely how many sentences Austen wrote coheres with any set of beliefs and we may safely assume that none will ever cohere with a set of beliefs. Opponents of the coherence theory will conclude that there is at least one true proposition which does not cohere with any set of beliefs.

Some versions of the coherence theory are immune to the transcendence objection. A version which holds that truth is coherence with the beliefs of an omniscient being is proof against the objection. Every truth coheres with the set of beliefs of an omniscient being. All other versions of the theory, however, have to cope with the objection, including the view that truth is coherence with a set of propositions believed at the limit of inquiry. Even at the limit of inquiry, finite creatures will not be able to decide every question, and truth may transcend what coheres with their beliefs.

Coherence theorists can defend their position against the transcendence objection by maintaining that the objection begs the question. Those who present the objection assume, generally without argument, that it is possible that some proposition be true even though it does not cohere with any set of beliefs. This is precisely what coherence theorists deny. Coherence theorists have arguments for believing that truth cannot transcend what coheres with some set of beliefs. Their opponents need to take issue with these arguments rather than simply assert that truth can transcend what coheres with a specified system.

The Identity Theory of Truth

The simplest and most general statement of the identity theory of truth is that when a truth-bearer (e.g. a proposition) *is* true, there is a truth-maker (e.g. a fact) with which it is identical and the truth of the former *consists in* its identity with the latter. The theory is best understood by contrast with a rival such as the correspondence theory, according to which the relation of truth-bearer to truth-maker is correspondence rather than identity.

Section Links:

Sources

The theory is a response to certain intellectual pressures. One such pressure is the wish that there should be no gap between mind and world: that when we think truly, we think *what is the case*. Another is dissatisfaction with the correspondence theory of truth, of the sort expressed by Frege [Frege (1918), p. 3]:

> A correspondence, moreover, can only be perfect if the corresponding things coincide and so are just not different things. ... It would only be possible to compare an idea with a thing if the thing were an idea too. And then, if the first did correspond perfectly with the second, they would coincide. But this is not at all what people intend when they define truth as the correspondence of an idea with something real. For in this case it is essential precisely that the reality shall be distinct from the idea. But then there can be no complete correspondence, no complete truth. So nothing at all would be true; for what is only half true is untrue. Truth does not admit of more and less.

Frege then goes on to deploy a charge of circularity against the likely reply that all the correspondence theory requires is correspondence in a certain respect. He himself concluded that truth was indefinable; but some have thought it possible to formulate an identity theory of a recognizably Fregean sort.

[Return to Section Links]

A Genuine Theory?

This theory is notably absent from textbook discussions of truth; and there is controversy over whether it is a theory of truth at all. Those who think that it is not are likely to make one or both of the following objections: it is obviously absurd; no one has ever held it. The remainder of this section is devoted to considering these two objections.

Can the absurdity charge be met?

The identity theory is clearly absurd from the point of view of those who, for instance, believe that truth-bearers are sentences and truth-makers non-linguistic states of affairs. But it may be available to those who hold the kinds of metaphysical views which make truth-bearers and truth-makers more alike. (For ease of expression, I shall from now on use the vocabulary of ‘judgments’ and ‘facts’ for truth-bearers and truth-makers respectively, recognizing that these terms can be tendentious -- especially in expressing the views of philosophers who abjured them.)

Making judgments more like facts

Some philosophers have tried to make judgments more like facts. Russell, reacting against idealism, at one stage adopted a view of judgment which did not regard it as an intermediary between the mind and the world: instead, the constituents of judgments are the very things the judgments are about. This involves a kind of realism about judgments, and looks as though it offers the possibility of an identity theory of truth. But since both true and false judgments are equally composed of real constituents, truth would not be distinguished from falsehood by being identical with reality; an identity theory of truth is thus unavailable on this view of judgment because it would be rendered vacuous by being inevitably accompanied by an identity theory of falsehood. Those who have held this sort of view of judgments, such as Moore and Russell, have accordingly been forced to hold that truth is an unanalyzable property of some judgments. If one looks for an identity theory here, one finds what might be called an identity theory of judgment rather than of truth. [Less brutally condensed accounts of these matters can be found in Baldwin (1991), Candlish (1989) and Candlish (1996).]

Making facts more like judgments

Other philosophers, notably those who have held the idealist view that reality is experience, have implied that facts are more like judgments. One such is F.H. Bradley, who explicitly embraced an identity theory

of truth, regarding it as the only account capable of resolving the difficulties he finds with the correspondence theory. [See Bradley (1907).] The way he reaches it is worth describing in a little detail, for it shows how he could avoid allowing the theory to be rendered vacuous by an accompanying identity theory of falsehood.

Bradley argues that the correspondence theory's view of facts as real and mutually independent entities is unsustainable: the impression of their independent existence is the outcome of the illegitimate projection on to the world of the divisions with which thought must work, a projection which creates the illusion that a judgment can be true by corresponding to part of a situation: as, e.g., the remark ‘The pie is in the oven’ might appear to be true despite its (by omission) detaching the pie from its dish and the oven from the kitchen. His hostility to such abstraction ensures that, according to Bradley's philosophical logic, at most one judgment can be true -- that which encapsulates reality in its entirety. This allows his identity theory of truth to be accompanied by a non-identity theory of falsehood, since he can account for falsehood as a falling short of this vast judgment and hence as an abstraction of part of reality from the whole. The result is his adoption of the idea that there are degrees of truth: that judgment is the least true which is the most distant from the whole of reality. Although the consequence is that all ordinary judgments will turn out to be more or less infected by falsehood, Bradley allows some sort of place for false judgment and the possibility of distinguishing worse from better. One might argue that the reason the identity theory of truth remains only latent in Russell and Moore is the surrounding combination of their atomistic metaphysics and their assumption that truth is not a matter of degree.

For Bradley, then, at most one judgment can be fully true. But even this one judgment has so far been conceived as *describing* reality, and its truth as consisting in correspondence with a reality not distorted by being mentally cut up into illusory fragments. Accordingly, even this one, for the very reason that it remains a description, will be infected by falsehood unless it ceases altogether to be a judgment and *becomes* the reality it is meant to be *about*. This apparently bizarre claim becomes intelligible if seen as both the most extreme expression of his hostility to abstraction and a reaction to the most fundamental of his objections to the correspondence theory, which is the same as Frege's: that for there to be correspondence rather than identity between judgment and reality, the judgment must differ from reality and in so far as it does differ, to that extent must distort and so falsify it.

Thus Bradley's version of the identity theory turns out to be misleadingly so-called. For it is in fact an eliminativist theory: when truth is attained, judgments disappear and only reality is left. It is not surprising that Bradley, despite expressing his theory in the language of identity, talked of the attainment of complete truth in terms of thought's suicide. In the end, then, even the attribution of the identity theory of truth to one who explicitly endorsed it turns out to be dubious. [For a more detailed version of this section, see Candlish (1995). For other doubts about whether Bradley was an identity theorist, see Walker (1998).]

A metaphysically neutral identity theory

More recently there have been attempts, consciously taking inspiration from Frege, to defend a

metaphysically neutral version of the theory: holding that truth-bearers are the contents of thoughts, and that facts are simply true thoughts rather than the metaphysically weighty sorts of things envisaged in correspondence theories. That is, the identity is not conceived as a (potentially troublesome) relation between an apparently mind-dependent judgment and an apparently mind-independent fact. A claimed benefit of this version is that it is not immediately disabled by the inevitable accompaniment of an identity theory of falsehood. The difficulty for these attempts is to make out the claim that they involve a *theory* of truth at all, since they lack independent accounts of truth-bearer and truth-maker to give the theory substance. [See Candlish (1995), Dodd and Hornsby (1992), Dodd (1996), Hornsby (1997).]

The most thorough account of this type is found in Dodd (2000). But although this book in its very title proclaims its author's adherence to an identity theory, it actually defends a variety of deflationism: ‘truth is *nothing more than* that whose expression in a language gives that language a device for the formulation of indirect and generalized assertions’ (p. 133, emphasis Dodd's). What became of the identity theory? The answer lies in the fact that Dodd conceives his identity theory as consisting entirely in the denial of correspondence and the identification of facts with true thoughts. It actually has nothing to say about ‘the nature of truth’, as traditionally conceived, offering no definition of ‘is true’, no explanation of what truth consists in or of the difference between truth and falsehood. This theory is ‘modest’, to use Dodd's expression, as opposed to ‘robust’ identity theories which begin from the bipolar recognition of independent conceptions of fact (conceived as truth-maker) and proposition (conceived as truth-bearer) employed in correspondence theories, and then attempt in one way or another to eliminate the apparent gap between them. Dodd's view is that his ‘modest’ theory gets some bite from its opposition to correspondence theories; and he urges (as does Hornsby) that we should anyway scale down our expectations of what a theory of truth can provide. However, the history of identity theories of truth reveals them as tending to mutate into other theories when put under pressure, as one can see from the discussion in the present article. Dodd holds that this is a problem only for robust theories. Yet his theory also exemplifies a variety of this tendency: in the end, it evolves into deflationism.

Can the no-holder charge be met?

Although it is difficult to find a completely uncontroversial attribution of the identity theory, there is evidence of its presence in the thought of a few major philosophers. As one might expect, mystical philosophers attracted by the idea that the world is a unity express views which at least resemble the theory (for example, Plotinus, *The Enneads*: 5th Ennead, 3rd Tractate, §5; 5th Ennead, 5th Tractate, §2). Bradley may also fall into this category; in any case, he and Frege have already been mentioned. Bolzano and Meinong are other possibilities: Findlay, for example, believes Meinong to have held an identity theory, reminding us that on his view, there are no entities between our minds and the facts; facts themselves are true in so far as they are the objects of judgments. [See Findlay (1933), Ch. III sec. ix.] C.A. Baylis defended a similar account of truth in 1948, and Roderick Chisholm endorsed a recognizably Meinongian account in his *Theory of Knowledge*. A sketchy version of the theory is embraced in Woozley's *Theory of Knowledge*. There are also the attempts, once again already mentioned, to establish a metaphysically neutral version: these show that there can be no doubt that some philosophers have tried to defend something that they wished to call an identity theory of truth.

Thomas Baldwin argues that the identity theory of truth, though itself indefensible, has played an influential but subterranean role within philosophy from the nineteenth century onwards, citing as examples philosophers of widely different convictions. [See Baldwin (1991). One of his attributions is queried in Stern (1993), others in Candlish (1995).] Whether or not Baldwin is right -- and it is possible that the theory is no more than an historical curiosity -- the identity theory of truth in its full-blooded form may turn out to be best thought of as comparable to solipsism: rarely, if ever, consciously held, but the inevitable result of thinking out the most extreme consequences of assumptions which philosophers often just take for granted.

Francis Herbert Bradley

F.H. Bradley (1846-1924) was the most famous, original and philosophically influential of the British Idealists. These philosophers came to prominence in the closing decades of the nineteenth century, but their effect on British philosophy and society at large -- and, through the positions of power attained by some of their pupils in the institutions of the British Empire, on much of the world -- persisted well into the first half of the twentieth. They stood out amongst their peers in consciously rejecting the tradition of their earlier compatriots, such as Hume and Mill, and responding rather to the work of Kant and Hegel.

It is for his metaphysics that Bradley has become best known. He argued that our everyday conceptions of the world (as well as those more refined ones common among his philosophical predecessors) contain hidden contradictions which appear, fatally, when we try to think out their consequences. In particular, Bradley rejected on these grounds the view that reality can be understood as consisting of many objects existing independently of each other (pluralism) and of our experience of them (realism). Consistently, his own view combined monism -- the claim that reality is one, that there are no real separate things -- with absolute idealism -- the claim that reality consists solely of idea or experience. This vision of the world had a profound effect on the verse of T.S. Eliot, who studied philosophy at Harvard and wrote a Ph.D. thesis on Bradley.

On philosophers, however, Bradley's contributions to moral philosophy and the philosophy of logic were far more influential than his metaphysics. His critical examination of hedonism -- the view that the goal

of morality is the maximization of general pleasure -- was seminal and stands as a permanent contribution to the subject which can still be read with profit today. Some of the doctrines of his logic have become standard and unnoticed assumptions through their acceptance by Bertrand Russell, an acceptance which survived Russell's subsequent repudiation of idealist logic and metaphysics.

Other notable figures among the British Idealists were Bernard Bosanquet, Edward Caird, T.H. Green, Harold Joachim and J.M.E. McTaggart.

Life

Bradley was born on 30th January, 1846 in Clapham (then in the county of Surrey, since absorbed into a much expanded London). He was the fourth child and eldest surviving son of Charles Bradley, a prominent Evangelical preacher, and his second wife, Emma Linton. The family was talented and well connected: George Granville Bradley, a son from the first marriage, was successively Head Master of Marlborough College, Master of University College, Oxford, and Dean of Westminster Abbey; A.C. Bradley, a younger son from the second marriage, taught philosophy at Oxford until 1881, and, after moving to literary studies, held chairs at Liverpool and Glasgow, refused one at Cambridge, and became the most distinguished Shakespearean critic of his day. Charles Bradley's ‘Clapham Sect’ (as this actively evangelical humanitarian group was known at the time) had strong imperial connections, including among its members a Governor-General of Bengal, a Governor of Sierra Leone, several members of Parliament and a permanent head of the Colonial Office.

In 1856 F.H. Bradley's schooling began at Cheltenham College; in 1861 he was transferred to Marlborough College, then under his half-brother's Headship. While at Cheltenham he began learning German; he read at least some of Kant's *Critique of Pure Reason* while still at school, though it is not clear that this was in the original language. In the winter of 1862-3 he contracted typhoid fever (at one

stage expected to kill him), followed shortly by pneumonia. Surviving both, he was protected from further exposure to the rigours of English public school life by leaving Marlborough in 1863.

In 1865 Bradley entered University College, Oxford, as a Scholar, getting a first in classical moderations (Mods) in 1867 but only an unexpected second in *literae humaniores* (Greats) in 1869. A.E. Taylor, a later admirer of Bradley and sympathetic to his idealism, attributed his reverse in Greats to ‘the complete incapacity of examiners whose philosophical scriptures were the writings of John Stuart Mill to comprehend what philosophy meant to the brilliant younger men who were shortly to revolutionize philosophical studies in Great Britain.’ Whether or not this is true, there is certainly an undisguised contempt for Mill and his followers exhibited in Bradley's *Principles of Logic*. After more than one failure to obtain a college fellowship, he was in December 1870 elected to one at Merton College Oxford, tenable for life, with no teaching duties, and terminable only on marriage. He never married, and remained in his fellowship until his death.

In June 1871 Bradley suffered a severe inflammation of the kidneys which appears to have had permanent effects. It has been suggested, possibly with malice, that the Bradleys in general were disposed to hypochondria; be that as it may, he was prone thereafter to be incapacitated by cold, physical exhaustion or anxiety, and in consequence lived a retired life. He took an active part in the running of his college, but avoided public occasions, to the extent, for example, of declining an invitation to become a founding member of the British Academy. Collingwood records of Bradley in his *Autobiography*, ‘[A]lthough I lived within a few hundred yards of him for sixteen years, I never to my knowledge set eyes on him.’ This relative seclusion added an element of mystery to his philosophical reputation, a mystery enhanced by the dedication of some of his books to a person identified only by the initials ‘E.R.’

But although Bradley devoted himself to philosophy, so that the history of his public life is largely that of his books and articles, it is clear that his was not a narrowly bookish existence. To protect his health, he frequently escaped the damp chill of Oxford winters for the kinder weather of southern English and Mediterranean seaside resorts. His metaphysics, a striking combination of the rational and the mystical, makes more than grudging room for the life of the senses and emotions, and his writings, especially his posthumously published *Aphorisms*, could not be the work of a man whose experience had been confined to the study. He liked guns and disliked cats, indulging his preferences economically by using the former to shoot the latter in the college grounds at night.

Bradley's political views are said to have been conservative, though not of a narrowly doctrinaire kind. Although his writings reveal a religious temperament, he seems (judging by a letter of 1922) to have found the evangelical religiosity of his father's household oppressive, and, perhaps in consequence, the attitude to Christianity displayed later in his writings exhibits a certain ambivalence; on the whole, he appears to have been a freethinker. (To imagine growing up amongst the members of the Clapham Sect, we might use John Sutherland's suggestion that the characters of Edmund and Fanny in Jane Austen's *Mansfield Park* give us some idea of what they would have been like.)

Bradley's public recognition included the conferring of the honorary degree LL.D. by the University of

Glasgow (1883), election to membership of the Royal Danish Academy (1921), of the *Accademia dei Lincei* and the *Reale Istituto Lombardo* of Milan (1922), and election to an Honorary Fellowship of the British Academy (1923). In 1924, King George V bestowed on him, the first philosopher to be singled out for this very rare honour, the Order of Merit. Three months later, after a few days' illness, he died from blood poisoning on 18th September, 1924. He is buried in Holywell Cemetery, Oxford.

Reputation

As the above (by no means complete) account of his public recognition reveals, in his own day Bradley's intellectual reputation stood remarkably high: he was widely held to be the greatest English philosopher of his generation, and although the idealists were never a dominant majority, amongst some philosophers the attitude towards him seems to have been one almost of veneration.

This reputation began to collapse fairly quickly after his death. The reasons for this are complex, and include matters seemingly extraneous to philosophy itself, such as the reaction against British imperialism (whose moral and spiritual mission had been justified by some idealist philosophers and undertaken by their pupils) following the Great War. One more locally significant factor was the tendentious but still damaging accounts of his views which appeared in the writings of Moore and Russell following their defection from the idealist camp. Another was logical positivism: for example, in the first chapter of A.J. Ayer's anti-metaphysical tract *Language, Truth and Logic*, Bradley is presented solely as a metaphysician and, on the basis of a single out-of-context sentence, selected for ridicule. Consequent upon such influences was a change, inimical to idealism, in the whole style of doing philosophy, a change characterized by the development of formal logic and the new respect paid to the deliverances of common sense and of ordinary language. Bradley's highly wrought prose and his confidence in the metaphysician's right to adjudicate on the ultimate truth began to seem alien to a later generation of philosophers reared on a mixture of plain talk and formalization and encouraged to defer to mathematics and empirical science.

Such influences ensured that a misleading and dismissive stereotype of Bradley became current among analytic philosophers and established in their textbooks, so that serious discussion of his work largely disappeared. One result has been that, despite his seminal influence on Russell and their extended controversy over fundamental matters, books and articles on Russell can contain few or even no references to Bradley. Another is that the incidental textbook references to some of Bradley's most characteristic, original and significant views, e.g. on relations and on truth, are often based on hostile caricatures. With a few exceptions (for instance, McTaggart's argument for the unreality of time), discussion of the work of the idealists has been sparse since the nineteen thirties. Discussion of Bradley began to revive, as did his reputation, in the nineteen seventies. At the time of writing it is clear that he is still widely underrated; it is, however, far from clear that his reputation will ever again stand as high as it did in his own lifetime.

Philosophy of History

Bradley's first substantial contribution to philosophy was the publication in 1874 of his pamphlet ‘The Presuppositions of Critical History’. Although it was not widely noticed at the time, it did have an impact on the thinking of R.G. Collingwood, whose epistemology of history, like Bradley's, evinces a certain scepticism concerning historical facts and the authority of testimony, and it has had a considerable subsequent influence. Bradley's views were inspired by his reading of German biblical critics, and such views have been prominent since in religious studies, where a reluctance to take at face value testimony of the occurrence of miracles which violate the laws of nature is appropriate. But Bradley's attempt to extend this reluctance to historical reports in general underestimates the contrast between the uniformity of nature and the variety of human history.

Although its overall argument cannot be regarded as satisfactory, the pamphlet is nevertheless worth reading both for its historical significance and for its value as a fairly brief introduction to Bradley's thought. Some characteristic later themes, such as the fallibility of individual judgments and the rejection of correspondence accounts of truth, here make an early appearance; and Bradley's philosophical style -- often obscure, typically disdainful of illustrative example, and by late twentieth-century standards uncomfortably literary -- can be seen in high relief.

[Return to Section Links]

Ethics

Bradley's views on ethics were expressed at length in his first widely acknowledged publication, *Ethical Studies* (1876). One reason it was noticed is that the book is highly polemical. (Sidgwick called it ‘vehemently propagandist’ in his *Mind* review.) He did not change these views significantly in later years: in 1893 he described it as ‘a book which, in the main, still expresses my opinions’ (*Appearance and Reality*, p. 356n) and at the time of his death was working on a second edition which, characteristically, was to retain the original text intact but incorporate additional matter.

Bradley says in his Preface that his object is ‘mainly critical’ and that the ethical theory of his time rests on ‘preconceptions metaphysical and psychological’, which are ‘confused or even false’. In this the most Hegelian of his books, his approach is, in a series of connected essays, to work dialectically through these erroneous theories towards a proper understanding of ethics. Accordingly he tells us that the essays ‘must be read in the order in which they stand’, and a corollary of this is that the common practice of extracting one or two of them (usually the brilliantly written ‘Pleasure for Pleasure's Sake’ and ‘My Station and Its Duties’) from the whole, on the basis of their individual merits, can result in a misleading impression of their significance within Bradley's moral thinking: neither represents some finished

position.

The development of this proper understanding begins by examining the ‘vulgar’ notion of moral responsibility and the apparent threats to it posed by the philosophical doctrines of determinism and indeterminism, threats which he argues evaporate once we examine the reality of human action. (A prominent theme in the book is that everyday moral thought is not to be overturned by moral philosophy.) It proceeds by turning to the question ‘Why should I be moral?’, which he answers by suggesting that the moral end for each of us is self-realization. What this is, is then gradually unfolded through examination of representative philosophical theories each of which is rejected as unsatisfactory because of its one-sided concentration upon particular features of the moral life. Nevertheless, he thinks, each theory captures something important which must not be forgotten in the proper understanding he aims at. For example, in the third essay, ‘Pleasure for Pleasure's Sake’, a still-classic critique of hedonistic utilitarianism, Bradley argues that its individualism is insupportable, as is its hedonistic conception of happiness as a pleasurable state identifiable independently of the means by which it is attained (so that it could in principle be achieved more conveniently than through moral behaviour). But purged of these errors, the essential utilitarian insight of the importance of happiness as the point of morality can be retained. Likewise, in the next essay's examination of a Kantian (if not quite Kant's) ethics of duty, he argues that from this conception of morality we should abandon, as the result of a false abstraction, its idea that duty should be done just for duty's sake. We can, however, retain the insight that morality requires the performance of individual *duties*, provided we are clear that their obligatoriness arises from the nature of each duty rather than from some formal principle.

These theories are inadequate because they have a deficient conception of the self, a deficiency he begins to remedy in the fifth essay, the famous ‘My Station and Its Duties’, where he outlines a social conception of the self and of morality with such vigour that it is understandable that the mistaken idea that it expresses his own position has gained some currency. This Hegelian account of the moral life, in which the self is fully realized by fulfilling its role in the social organism which grounds its duties, is clearly one which greatly attracted Bradley, and he seems never to have noticed the implicit tension between the metaphysical account of the self as necessarily social and the moral injunction to realize the self in society. But he finally acknowledges its inadequacy, pointing out, for instance, that any actual society may exhibit moral imperfections requiring reform from the standpoint of an ideal which cannot be exemplified in the roles available within that society. This leads him naturally into the next essay's consideration of ideal morality, where he discusses the scope of morality's demands on the individual, and, by a further natural extension, into the seventh essay's discussion of the distinction between the good and the bad self, a discussion which involves an attempted demonstration that the bad self is a kind of unrealizable parasite on the good. This is necessary to his enterprise: without it, he could not hope to make plausible his suggestion that the aim of morality is self-realization. But in one way the enterprise still founders: the final essay argues that morality is ultimately self-contradictory, depending for its existence on the evil it seeks to overcome. Realization of the ideal self is thus unattainable through morality, but the book closes by suggesting that it is still possible in religion.

Some of Bradley's metaphysical ideas are displayed in his defence of his moral philosophy. An example is his claim that the self is a concrete universal and that the ethical doctrines he criticizes are damaged by

their reliance upon abstract notions of the self. The self is *universal* in that it retains its identity over time and through many different actions, thus collecting together the series of abstract particulars which make up its history in a way analogous to that in which the abstract universal *red* collects together its scattered individual instances (now often called ‘tropes’); it is *concrete* in that, unlike *red* it is a real non-abstract individual. For such claims to be fully convincing, a developed system in which the underlying metaphysical ideas are fully worked out is needed, as he himself admitted. But in this later working out, most of it in *Appearance and Reality*, the expression ‘concrete universal’ almost disappears from Bradley's vocabulary, mainly because he eventually concludes that there can be only one such thing; nevertheless, the idea involved remains, reappearing in the form of the recurring theme that abstraction is falsification, and in this form is central to his logic and his metaphysics.

[Return to Section Links]

Logic

Bradley's most sustained treatment of logic comes in *The Principles of Logic*, published contemporaneously with Frege's *Grundlagen*. The benefit of hindsight provides a striking contrast between these works, the former apparently looking back to the nineteenth century, the latter anticipating the twentieth. While both books eschew formal methods, in Frege's case this results merely from an attempt to give a readable account of some applications of mathematical logic. But the absence of formulae (theorems, axioms, rules of inference) from Bradley's book is intrinsic to it, expressing an opposition (shared by Mill) to the formalization of reasoning *in principle*, as detaching inference from the practical acquisition of scientific knowledge. This, together with the fact that familiar terms (e.g. ‘contradiction’) are used in unfamiliar ways, gives the book an archaic feel. Nevertheless, and despite the fact that *Principles* would no longer ordinarily be consulted by a modern logician unless for historical purposes, it focuses on issues central to logic, and the impression of its being backward-looking is to some extent misleading: for example, it uses the older vocabulary of ‘ideas’ and ‘judgments’ to express views which, often through their (selective) impact upon Russell, gave rise to doctrines subsequently expressed in terms of sentences and propositions; and it effectively exposed the notion of meaning to a sceptical scrutiny which has continued long since.

Although the treatment is less rigidly dialectical than that of *Ethical Studies,* Bradley develops his views through criticism of others, and alters them as he goes along. One result is that the book is far from easy to *consult*, and a reader determined to find out what Bradley thinks must be prepared to follow its argument through many twists and turns.

Traditionally, logic books came divided into three parts, dealing respectively with Conception (usually via *ideas*, the traditional components of judgments), Judgment and Inference. Bradley both inherits and transforms this tradition, keeping the three-part format but devoting the first to Judgment and both second and third parts to Inference, thus dropping the separate treatment of Conception. This is significant in that it reflects his rejection of the standard view that judgments are formed by somehow conjoining ideas: for example, the Port-Royal *Logic*'s Aristotelian claim that they are ‘necessarily

composed of three elements -- the subject-idea, the attribute, and the joining of these two ideas'. Bradley attacks such doctrines on more than one front.

He argues, for instance, that those who, like Hume, think judgments to consist of separable ideas, fail to identify the sense of 'idea' in which ideas are important to logic: ideas in this sense are not separate and datable psychological events (such as my now visualizing a rainbow) but abstract universals. Once ideas are properly understood, he suggests, they can no longer even plausibly be thought of as individual and mutually independent entities which can be put together to create a judgment (as Locke maintains in Chapter XIV of Book IV of *An Essay Concerning Human Understanding*): the order of dependence is the opposite, ideas being abstractions from complete judgments. Here, albeit in his archaic vocabulary, Bradley identifies in advance the difficulties which Russell was later to face in trying to reconcile the unity of the proposition with what he thought to be the mutual independence of its constituents, difficulties which appeared in another guise for Frege in his attempt to maintain a strict division between concepts and objects.

Further, given that ideas are universals, accounts like that of Port-Royal make it impossible to see how judgment can be about reality, since its ideas represent kinds of things, while those real things themselves are particular; so long as judgment is confined to ideas, there can be no unique identification of any item about which we judge. Bradley applies the point to language, arguing that even grammatically proper names and demonstratives are disguised general terms. He thus anticipates that application of Russell's Theory of Descriptions in which it is used to eliminate grammatical names in favour of quantified general sentences. Whether or not this is actually the origin of that theory, there is no doubt in another case: Russell, who claimed in correspondence to have read *Principles* closely, acknowledged openly that he was convinced by Bradley's argument that the logical form of universal sentences is hypothetical (so that, e.g., 'All cows eat grass' is to be understood as saying 'If anything is a cow then it eats grass'). In this way, Bradley had a significant, if indirect, impact on predicate calculus.

Bradley's own account of judgment is that it is 'the act which refers an ideal content ... to a reality beyond the act', so that the logical form of every judgment is 'Reality is such that, if anything is S then it is P'. This formulation makes intelligible what is superficially paradoxical in Bradley, when he says: 'All judgments are categorical, for they all do affirm about the reality, and assert their content of that. Again, all are hypothetical, for not one of them can ascribe to reality its content unconditionally' (*Principles*, Bk I, Ch. II, sec. 79, modified according to Bradley's notes to the Second Edition). It is not hard to see in this an informal anticipation of the representation of sentences in terms of a combination of universal quantifier and object- and predicate-variables. (Here as elsewhere the book looks forward as well as back.) But it is an exaggeration to claim, as some have done, that Bradley's strictures on the account of judgment as a combination of ideas mean that he is straightforwardly opposed to psychologism in logic, for it is clear that he thinks logic's subject matter to be mental acts, not sentences or statements.

Bradley continues to criticize traditional logic when he turns from judgment to inference. Just as he rejected the Aristotelian account of judgments as combinations of subject and predicate, he rejects Aristotelian syllogistic (for the same reason as he later rejects Mill's canons of induction): it misses the fact that reasoning can take place only through the generality involved in universals. Universals are thus

essential to inference, and for this reason Hume's account of inference in terms of the association of ideas collapses: Humean ideas are particulars, fleeting episodes which cannot be revived by association. This does not mean that association of ideas is impossible, but genuine association (which Bradley calls ‘redintegration’) can involve only universals.

Surprisingly for those who subscribe to the common view, first broadcast by Russell in 1900 in *A Critical Exposition of the Philosophy of Leibniz* and much repeated thereafter, that Bradley thought all judgments to be of subject/predicate form and accordingly failed to recognize relational judgments as a distinct kind, Bradley's treatment of inference includes the complaint that the mathematical logics of his time cannot represent valid relational inferences. His own initial account of inference is that it is ‘ideal experiment’: ‘ideal’ in that these are thought-experiments which remain in the realm of idea, but nevertheless experiments in that their results are not guaranteed in advance by a complete set of logical laws which infallibly determine their own application (a view reminiscent of Wittgenstein). But later, after a long and tangled consideration of the question of how it is possible for a deductive inference to be reflected in reality, he comes up with a revised account: ‘Every inference is the ideal self-development of an object taken as real’ (*Principles*, Terminal Essay I, p. 598). Bradley seems here to be following the Humean idea that there are no logical relations between distinct existences: the reason that valid inference can be reflected in reality is that it can never take one beyond the original subject matter.

Much of *The Principles of Logic* is polemical, and it affords occasional examples of Bradley at his funniest and most acerbic, such as this note to a short chapter criticizing Herbert Spencer's view of the nature of inference (Bk II, Pt II, Ch. II, sec. 14, n. 3),

> With regard to Mr. Spencer's view I would suggest, as a possibility, that it never was taken from the facts, but was a development of or from something about Comparison which he found in Hamilton. Reading so few books, Mr. Spencer was naturally more at the mercy of those he did read.

and this passing swipe at Hamilton himself (Bk II, Pt II, Ch. I, sec. 9),

> This may be called the law of Redintegration. For we may take this name from Sir W. Hamilton (*Reid*, p. 897), having found nothing else that we could well take.

It is clear that much of Bradley's criticism of his predecessors and contemporaries expresses his hostility to the sort of psychological atomism evident in extreme form in Hume but equally to be found presupposed in accounts of judgment like those mentioned above. What Bradley particularly objected to about such views is that the particulars (ideas) which they treated as realities in their own right, and out of which judgments are said to be composed, are anything but: far from being themselves genuine individuals, they are abstractions from the continuous whole of psychological life and incapable of independent existence. This is an early version of a holism which has since had many adherents. But he then goes on to point out that judgments too involve abstractions, since the subject matter of any judgment is necessarily detached from its background (as, for example, ‘Julius Caesar crossed the

Rubicon' detaches the river from its location and the general from his army) and this process inevitably misrepresents the way things really are. Thus the objections which Bradley deployed against misleading accounts of logic now begin to pose a threat against logic itself by eroding the integrity of the judgments which go into its inferences, and he ends *Principles* appropriately by suggesting that no judgment is ever really true nor any inference fully valid.

At this point Bradley's attempt to write a book on logic without getting entangled in metaphysics begins to succumb to his doubts about the notion of truth. He holds that logic presupposes a correspondence theory of truth (he calls it the 'copy' theory), but it is apparent that he thinks this theory metaphysically inadequate: indeed, he marshals against it counter-examples drawing on, e.g., disjunctions, counter-examples which had to await the theory of truth-functions before they could be accommodated. In *Essays on Truth and Reality* he takes these ideas further, arguing for 'the identity of truth knowledge and reality'. It could hardly be more clear that Bradley holds an identity theory of truth, and although he is commonly believed to have been a supporter of a coherence theory of truth (and is standardly identified as such in the textbooks), this common belief is at the very least greatly misleading. However, the combination of the identity theory and his metaphysical doctrine that reality is a unified whole enables coherence to be deduced from his views as a consequence, and he himself thought the *test* of truth to be 'system', a notion under which he included what is commonly meant by coherence; this explains why he has so often been thought to be a coherence theorist. It might be thought that his famous attack on the Hegelian idea that the rational is the real (*Principles* Bk III, Pt II, Ch. IV, sec. 16) is inconsistent with his holding an identity theory of truth: but the two are reconciled through his doctrine of degrees of truth, a doctrine which has to be understood within the context of his metaphysics.

[Return to Section Links]

Metaphysics

After the completion of *The Principles of Logic*, Bradley turned to the task of giving a full account of his metaphysics. The result was *Appearance and Reality* (1893). But Bradley was philosophically active for a further thirty years thereafter, continuing to elucidate, defend and refine his views, and engaging with critics and rivals (notably, and revealingly for both sides, with Russell). Concentration upon *Appearance and Reality* alone, therefore, risks placing undue weight upon what turn out to be temporary features of thought or expression, and this has in fact contributed to the distorted impressions of his thinking so often to be found in the textbooks of analytic philosophy.

Appearance and Reality is divided into two books. The first, 'Appearance', is brief, and its aim destructive, arguing that 'the ideas by which we try to understand the universe' all bring us ultimately to contradictions when we try to think out their implications. Some of these ideas belong especially to philosophy, such as the view that only the primary qualities are real; others, for instance the notions of cause, motion, self, space, thing and time, are deployed in everyday life. The second book, 'Reality', is long; its aim is to provide a positive account of the Absolute -- the ultimate, unconditioned reality as it is in itself, not distorted by projection through the conceptual mechanisms of thought. A large proportion of

his discussion is devoted to consideration of natural objections to this positive account.

Much of Book I involves presentation of familiar suggestions which make only part of Bradley's case: he alleges, for example, that motion involves paradoxes, and that primary qualities alone cannot give us reality, for they are inconceivable without secondary qualities. But Chapter III, entitled ‘Relation and Quality’, is uniquely Bradleian, alarming in the breadth of its implications, and has caused intermittent controversy ever since. In generalized form, its contention is that relations (such as *greater than*) are unintelligible either with or without terms, and, likewise, terms unintelligible either with or without relations. Bradley himself says of the arguments he wields in support of this contention,

> The reader who has followed and has grasped the principle of this chapter, will have little need to spend his time on those which succeed it. He will have seen that our experience, where relational, is not true; and he will have condemned, almost without a hearing, the great mass of phenomena.

And it is clear that his views on relations are both highly controversial and central to his thought.

In view of this, it was a serious tactical error on Bradley's part to present his arguments so sketchily and unconvincingly that even sympathetic commentators have not found it easy to defend him, while C.D. Broad was able to say later, ‘Charity bids us avert our eyes from the pitiable spectacle of a great philosopher using an argument which would disgrace a child or a savage.’

The impression that Bradley's crucial metaphysical arguments are negligible arises in part from reading them as designed to prove the doctrine of the internality of all relations (i.e., their reducibility to qualities, or their holding necessarily, depending on the sense of ‘internal’, Russell having interpreted the doctrine in the former way, Moore in the latter). Whichever sense we take, this is a misreading -- and an impossible one, if we take ‘internal’ in Russell's sense, because of Bradley's rejection of the subject/predicate account of judgment. If, however, we use Moore's sense of ‘internal’, the reading is understandable: in Chapter III Bradley confusingly applies this word to relations in a metaphysically innocent way which has no connection with the doctrine of internality, without drawing attention to this fact; while in other parts of *Appearance and Reality* he openly flirts with the doctrine of internality, repudiating it clearly only in later works less often read, such as the important essay ‘Relations’ left incomplete at his death. Further, Bradley does uniformly reject the reality of external relations, and it is natural, though not logically inevitable, to interpret this as a commitment to the doctrine of internality.

His considered view, though, is that neither external nor internal relations, nor yet their terms, are real; and that is the proper conclusion of his arguments in the chapter in question, arguments which he deploys as a team, systematically excluding the possible positions available to those who would disagree. The member of this team which has attracted the greatest attention is the one which alleges that if a relation were a further kind of real thing along with its terms (as, e.g., Russell later assumed in his multiple relation theory of judgment), then a further relation would be required to relate it to its terms, and so on *ad infinitum*. It is clear from this argument (which is an obvious descendant of *The Principles of Logic*'s

attack on the traditional analysis of judgment), as well as from his own explanation, that for him ‘real’ is a technical term: to be real is to be an individual substance (in the sense commonly found in Descartes, Leibniz and Spinoza), so that to deny the reality of relations is to deny that they are independent existents. It is this which explains reactions like Broad's: in common with others, he took Bradley to be assuming that relations are a kind of object, when what Bradley was doing was arguing by a kind of *reductio* against that very assumption.

Some, however, have thought that the denial of the reality of relations amounts to the assertion that all relational judgments are false, so that it is, for example, not true that 7 is greater than 3 or that hydrogen is lighter than oxygen. Such an interpretation is made credible by Bradley's account of truth, for on that account no ordinary judgment is ever perfectly true; in consequence, to one who reads him under the influence of the later but anachronistic assumption that truth is two-valued, his claim appears to be that relational judgments are all false. On Bradley's account of truth, however, while for ordinary purposes it is true that 7 is greater than 3 and false that oxygen is lighter than hydrogen, once we try to meet the more exacting demands of metaphysics we are forced to recognize that truth admits degrees and that, while the former is undoubtedly more true than the latter, it is not fully true. The imperfection of even the more true of these judgments, though, is nothing to do with the its being relational rather than predicative. For, as was observed above in the section on Logic, Bradley thought all judgments to be defective in that representation can proceed only on the basis of separating in thought what is not separate in reality: when, for example, we say ‘These apples are hard and sour’, we not only implicitly abstract the apples from their container but detach the hardness and sourness from each other and abstract them from the apples themselves. A perfect truth, one completely faithful to reality, would thus have to be one which did not abstract from reality at all; and this means that it would have to be identical with the whole of reality and accordingly no longer even a judgment. The final truth about reality is, on Bradley's view, quite literally and in principle inexpressible.

It is, however, possible to give an outline. The impression of reality's consisting of a multiplicity of related objects is a result of the separations imposed by thought; in fact ‘the Absolute is not many; there are no independent reals.’ (All quotations from here on are from *Appearance and Reality*, Ch. XIV.) Reality is one -- but one what? Experience, he says, in a wide sense of the term: ‘Feeling, thought and volition (any groups under which we class psychological phenomena) are all the material of existence, and there is no other material, actual or even possible.’ The immediate argument he gives for this unintuitive doctrine is brief to the point of offhandedness, merely challenging the reader to think otherwise without self-contradiction; his greater concern is to make it quite clear that this experience does not belong to any individual mind, and his doctrine not a form of solipsism. But he is not quite as offhand as he appears, for he soon makes clear that he thinks the whole book to be a best-explanation argument for this objective (or absolute) idealism: ‘This conclusion will, I trust, at the end of my work bring more conviction to the reader; for we shall find that it is the one view which will harmonize all facts.’

So ‘the Absolute is one system, and ... its contents are nothing but sentient experience. It will hence be a single and all-inclusive experience, which embraces every partial diversity in concord. For it cannot be less than appearance, and hence no feeling or thought, of any kind, can fall outside its limits.’ But how

can we understand this diversity to be possible, when it cannot be accounted for through terms and relations? Bradley's answer is that we cannot understand this in detail, but can get some grasp on what he means by considering a pre-conceptual state of immediate experience in which there are differences but no separations, a state from which our familiar, cognitive, adult human consciousness arises by imposing conceptual distinctions upon the differences. Reality is like this primitive state, but not exactly like, for it transcends thought rather than falls short of it, and everything, even conceptual thought itself, is included in one comprehensive and harmonious whole. Appearances thus contribute to Reality in a fashion analogous to the ways in which segments of a painting contribute to the whole work of art: detached from their background, they would lose their significance and might in isolation even be ugly; in context, they can themselves be beautiful and make an essential contribution to the beauty and integrity of the whole. Such limited comparisons are all the help we can get in understanding the Absolute and its relation to its appearances: Bradley rejects as impossible the demand for detailed explanations of how phenomena like error and evil belong to the Absolute, instead trying to shift the burden of proof to critics who express confidence in their incompatibility. His general answer is that anything that exists, even the worst of evils, is somehow real: the Absolute must comprehend both evil and good. But, just as truth admits of degrees, a judgment being less true the further it is from comprehending the whole of reality, so (consistent with ‘the identity of truth knowledge and reality’) reality itself admits of degrees, a phenomenon being the less real the more it is just a fragmentary aspect of the whole. The Absolute is in such a way further from evil than from good, but is itself neither, transcending them both as it transcends even religion -- it is in a sense a Supreme Being, but not a personal God.

In Bradley's often rhapsodic descriptions of the Absolute, a conception of the world based both on his sceptical scrutiny of the inadequacies of philosophers' accounts of judgment and, it is clear, on a kind of personal experience of a higher unity which in another context might have made him one of the world's revered religious mystics, we can see why, at the start of this article, his metaphysics was described as ‘a striking combination of the rational and the mystical’. The very idiosyncrasy of this combination has meant that few philosophers have been convinced by it. Nevertheless, in its bold and direct confrontation of what he called ‘the great problem of the relation between Thought and Reality’, it stands in Western philosophy as a permanent and unsettling challenge to the capacity of discursive thought to display the world without distortion; unsettling because it arises, not from the imposition of an external standard which could be rejected as arbitrary or inappropriate, but from the demand that our mechanisms of representation meet the standards they themselves implicitly set.

Bibliography

Works by Bradley

- *Ethical Studies* (London: Oxford University Press, 1876; second edition, with notes: London: Oxford University Press, 1927).

- *The Principles of Logic* (London: Oxford University Press, 1883; second edition, revised, with commentary and terminal essays, London: Oxford University Press, 1922; corrected impression, 1928).
- *Appearance and Reality* (London: Swan Sonnenschein, 1893; second edition, with an appendix, London: Swan Sonnenschein, 1897; ninth impression, corrected, Oxford: Clarendon Press, 1930).
- *Essays on Truth and Reality* (Oxford: Clarendon Press, 1914).
- *Aphorisms* (Oxford: privately printed at the Clarendon Press, 1930).
- *Collected Essays* (Oxford: Clarendon Press, 1935).
- *Writings on Logic and Metaphysics* edited and with introductions by James W. Allard and Guy Stock (Oxford: Clarendon Press, 1994).
- *The Collected Works of F.H. Bradley*, 12 volumes, edited and introduced by W.J. Mander and Carol A. Keene (Bristol: Thoemmes, 1999).

The more recent of the editions produced in Bradley's lifetime are the ones now usually cited and the most useful: while the earlier text is left intact, Bradley's later thoughts are added in the form of notes, appendices and essays, enabling the reader to trace the changes in his ideas. (Such additional material is particularly extensive in the *Logic*, where Bradley frequently defers to Bosanquet's criticisms of the first edition.) *Collected Essays* contains the two pamphlets ‘The Presuppositions of Critical History’ (1874) and ‘Mr Sidgwick's Hedonism’ (1877) as well as the valuable unfinished essay on relations (1923-4) and a good bibliography. Between them, this book and the important *Essays on Truth and Reality* contain all his articles of any substance; these are the versions normally cited. *Aphorisms*, after many years out of print, appeared in 1993 (bound together with ‘Presuppositions of Critical History’ and an introduction by Guy Stock) in a facsimile edition (Bristol: Thoemmes Press). Bradley's unpublished papers, notebooks and letters received are in the library of Merton College, Oxford. Correspondence between Bradley and Russell is in the Russell Archives at McMaster University; interesting extracts appear on pp. 349-353 of Volume 6 of *The Collected Papers of Bertrand Russell* (London: Routledge 1992). The John Rylands Library of the University of Manchester has letters from Bradley to Samuel Alexander. Much previously unpublished material has been made available in the 1999 *Collected Works*.

- Wollheim, R. (1969) *F.H. Bradley* (Harmondsworth: Penguin), second edition.

There is also a journal, *Bradley Studies*, which (in its own words) "aims to publish critical and scholarly articles on philosophical issues arising from Bradley's writings and from those of related authors [and] to include each year an ongoing list of what has been published on Bradley and related themes." The journal is distributed to all members of the Bradley Society as a part of their annual membership, but may also be bought separately by individuals and institutions. Enquiries about the journal should be directed to its Editor William Mander.

Bernard Bosanquet

Bernard Bosanquet (1848-1923), British philosopher, political theorist and social reformer, was one of the principal exponents (with F.H. Bradley) of late nineteenth and early twentieth century 'Absolute Idealism.'

Life

Bernard Bosanquet was born on July 14, 1848 in Rock Hall (near Alnwick), Northumberland, England. He was the youngest of five sons of the Reverend Robert William Bosanquet by the latter's second wife, Caroline (MacDowall). Bernard's eldest brother, Charles, was one of the founders of the Charity Organization Society and its first Secretary. Another brother, Day, was an Admiral in the Royal Navy and served as Governor of South Australia. Yet another, Holford, was elected to the Royal Society and was a fellow of St John's College, Oxford.

Bosanquet studied at Harrow (1862-1867) and at Balliol College, Oxford (1867-1870), where he fell

under the influence of idealist ‘German’ philosophy, principally through the work of Edward Caird and T.H. Green. (Green described him as "the most gifted man of his generation.") Bosanquet received first class honors in classical moderations (1868) and *literae humaniores* (1870) and, upon graduation, was elected to a Fellowship of University College, Oxford, over F.H. Bradley. While at University College, Bosanquet taught the history of logic and the history of moral philosophy; his only published work during this time was a translation of G.F. Schoemann's *Athenian Constitutional History*.

Upon receipt of a small inheritance in 1881, Bosanquet left Oxford for London, where he became active in adult education and social work through such organizations as the London Ethical Society (founded 1886), the Charity Organisation Society, and the short-lived London School of Ethics and Social Philosophy (1897-1900). During this time he met and married (in 1895) Helen Dendy, an activist in social work and social reform, who was to be a leading figure in the Royal Commission on the Poor Laws (1905-1909).

While in London, Bosanquet was also able to engage in philosophical work, and many of his major publications date from this time. Some of them--such as *The Philosophical Theory of the State* and *Psychology of the Moral Self*--were developed from lectures that he gave to adult education groups. He was an early member of the Aristotelian Society, and served as its Vice President (1888) and President (1894-1898).

At the age of 55, Bosanquet briefly returned to professorial life, as Professor of Moral Philosophy at the University of St Andrews in Scotland (1903-1908), but his health was not good and he wished to devote more time to original philosophical writing. He retired to Oxshott, Surrey, where he nevertheless remained active in social work and philosophical circles. In 1911 and 1912, Bosanquet was elected Gifford Lecturer in the University of Edinburgh. The text of these lectures--*The Principle of Individuality and Value* and *The Value and Destiny of the Individual*--serve as the most developed statement of his metaphysical views. It is important for a proper understanding of Bosanquet's philosophy that one recognize that the elaboration of his metaphysics came some time *after* his work in ethics, social work and political philosophy.

The publication of the Gifford lectures incited a good deal of critical reaction to Bosanquet's views, particularly in metaphysics (e.g., on the ‘idealism/materialism’ controversy and on the nature of finite individuality), logic (e.g., concerning the status of propositions and the nature of inference), and ethics. Despite his vigorous participation in such exchanges, present throughout Bosanquet's work is his desire to find common ground among philosophers of various traditions and to show relationships among different schools of thought, rather than to dwell on what separates them.

In spite of the challenges to idealism from both within and outside of the academic world, discussion of Bosanquet's work continued through the early decades of the 20th century. He died in his 75th year in London on February 8, 1923.

At the time of his death, Bosanquet was arguably "the most popular and the most influential of the

English idealists" (J.H. Randall). He was the author or editor of more than 20 books and some 150 articles. The breadth of his philosophical interests is obvious from the range of topics treated in his books and essays--logic, aesthetics, epistemology, social and public policy, psychology, metaphysics, ethics and political philosophy. For his contributions to philosophy and to social work, he had been made a Fellow of the British Academy in 1907, and had received honorary degrees from Glasgow, Birmingham, Durham, and St Andrews.

Bosanquet was one of the earliest philosophers in the Anglo-American world to appreciate the work of Edmund Husserl, Benedetto Croce, Giovanni Gentile and Emile Durkheim, and the relation of his thought to that of Ludwig Wittgenstein, G.E. Moore and Bertrand Russell is significant, though still largely unexplored. Although F.H. Bradley is today far better known in philosophical circles, in his obituary in the *Times*, Bosanquet was said to have been "the central figure of British philosophy for an entire generation."

General Background

Bosanquet's philosophical views were in many ways a reaction to 19th century Anglo-American empiricism and materialism (e.g., that of Jeremy Bentham, John Stuart Mill and Alexander Bain), but also to that of contemporary personalistic idealism (e.g. that of Andrew Seth Pringle-Pattison, James Ward, Hastings Rashdall, W.R. Sorley, and J.M.E. McTaggart) and organicism (e.g. Herbert Spencer). Bosanquet held that the inspiration of many of his ideas could be found in Hegel, Kant, and Rousseau and, ultimately, in classical Greek thought. Indeed, while at the beginning of his philosophical career Bosanquet described Kant and Hegel as "the great masters who ‘sketched the plan’," he said that the most important influence on him was that of Plato. The result was a brand of idealist philosophical thought that combined the Anglo-Saxon penchant for empirical study with a vocabulary and conceptual apparatus borrowed from the continent. Bosanquet is generally considered to be one of the most ‘Hegelian’ of the British Idealists, though the extent to which the term ‘Hegelian’ is appropriate or illuminating in describing his work has been a matter of some recent debate.

More directly, Bosanquet's thought shows a number of similarities to that of T.H. Green, his teacher, and to Bradley, his contemporary. Bosanquet himself acknowledges that these similarities are far from coincidental. He frequently admits his debt to Green's works and, as late as 1920, he wrote that "since the appearance of Ethical Studies... I have recognized [Bradley] as my master; and there is never, I think, any more than a verbal difference or difference of emphasis, between us".

There is, however, at least some hyperbole in such comments. Bosanquet did not follow either Green or Bradley blindly, and there are important differences in his work. While he defended Green's ethical theory and many of Green's conclusions, he addressed a number of issues never dealt with in Green's corpus. Moreover, while it is clear that Bosanquet considered Bradley's work in metaphysics and ethics to have been momentous, this admiration was no doubt influenced by the fact that Bradley's philosophy and method reflected interests and an approach that Bosanquet had arrived at quite independently.

Principal Contributions

Religion

Bosanquet's philosophical views on religion were in large part influenced by early nineteenth century biblical studies--initially, mediated through the writings of his Oxford tutors, Edward Caird and Benjamin Jowett.

The work of David Strauss, Ferdinand Baur, and others, at the beginning of the nineteenth century, marked a turn in the scholarly approach to religion and scripture, towards what is now called ‘the scientific study of religion.’ Religious experience, sacred texts, and religious practice were now to be seen as phenomena open to critical investigation and which could--and should--be examined independently of one's religious commitment, and according to the principles of literary and historical analysis. Strauss and his followers challenged the conflation of religious dogmas and creeds with original religious experience, and they were particularly doubtful whether one could recover much knowledge of such experience from ‘events’ recorded in scripture.

By the mid-nineteenth century, this approach to the study of religion had established itself in Britain, particularly in Oxford. Figures such as Jowett and Caird, and others in the Church of England ‘Broad Church movement’ (such as Frederick Temple, Bishop J.W. Colenso, and Thomas Arnold) argued for a more analytical and ‘rational’ approach to understanding religious belief--though they were frequently criticised for this by Church authorities.

The distinction of practice from dogma and experience from creeds was, however, also a feature of the evangelical movement within the Church of England. Bosanquet, like many of his fellow idealists, was raised in an Evangelical household; his later philosophical views, then, can be seen as a continuation, rather than an interruption or contradiction of, his early religious convictions.

Despite his conventional religious upbringing, Bosanquet was not an orthodox Christian. While he did claim that religion was not only central to one's life, but was that which made life worth living, he held that, taken literally or at face value, many particular religious beliefs are either incoherent or false. Bosanquet notes that, in religion, "rationalism, curiosity, metaphor, and deduction from metaphor, operate by way of distortion" (*What Religion Is*, p. 68), and that, to help one read biblical texts, one must engage in a hermeneutical enterprise, and ‘learn to interpret’ them--though, even here, he doubted whether ‘the sacred books of a Church can ever be understood in their actual meaning.’ Moreover, some religious beliefs do not mean what many take them to mean. Bosanquet argues, for example, that, if we examine the idea of God--who is often described as an ‘infinite individual--we will find that to attribute ‘infinity’ to a being would be inconsistent with "every predicate which we attach to personality." Finally, Bosanquet held that religious belief in general is not about some supernatural being or transcendent realm, entering into our daily lives. It focuses, rather, on what takes place in the world. His analysis of religion and religious belief is, then, ‘immanentist.’

Bosanquet distinguished religious beliefs about particular persons or events from ‘religion’ (or, what was the same thing for him, ‘religious belief as a whole’ or ‘religious consciousness’). Still, he did not see himself as either an agnostic or atheist, or as reducing ‘religion’ to the ‘ethical’. While he states that there is much in Christianity that is no longer intelligible, he insists that religion--in the sense of religious consciousness--is needed for morality, and that an ethics cut off from religion is "without sap or life." Similarly, Bosanquet's opposition to seeing religion or religious belief as a faith in something supernatural does not mean that he denied the existence of the spiritual or held a ‘reductionist’ view of reality. When it comes to human consciousness, he argued, the spiritual--the awareness of the infinite in our world--is at least as much a part of what exists as the material. This ‘infinite’ here is what Bosanquet called the ‘Absolute’.

Human beings are, Bosanquet noted, aware of something infinite that bears directly on their lives, and in his entry on ‘Philosophy of Religion,’ for J.M. Baldwin's *Dictionary of Philosophy and Psychology* (1902), he writes that it is this awareness, and one's commitment to "that set of objects, habits, and convictions, whatever it might prove to be, which [one] would rather die for than abandon, or at least would feel himself excommunicated from humanity if he did abandon" that constitutes what religion is. (While some idealists, such as Pringle-Pattison, seem to have held that such an Absolute is God, Bosanquet did not--though neither does he explicitly reject the existence of God.) Still, religious belief is neither the same as, nor tied essentially to, rituals and practices. Neither does it require adherence or assent to a set of propositions or dogmas--and certainly not to a set of propositions focusing on beings or events in the history of a community of believers. Religious belief is, in short, quite distinct from ‘theism.’

While one finds religious belief and religious consciousness throughout history and throughout the world, Bosanquet rejects the view that all religions are on a par. Religious consciousness has evolved and higher forms of religion--i.e., those which show a *unity* of the Divine and human nature--are the more ‘true.’ What Bosanquet is ultimately interested in, then, is religion in its highest or most developed form--what Caird called ‘Absolute Religion.’ Though Bosanquet does not develop what, specifically, this means, his Gifford lectures give some hint as to the direction of his thought.

Despite his criticisms of, and challenges to, Christianity, Bosanquet believed that the world had benefitted from Christian civilisation and culture, and that Christianity was a progress over ‘earlier’ stages of religion. Moreover, he not only frequently employs allusions to Christian religious belief and practice to illustrate his general views, but retains elements from Christian doctrine, such as the ideas of the atonement and of justification by faith--though in a highly modified form. The doctrines of the atonement (to which Bosanquet often referred, using the words of Goethe, as ‘dying in order to live’) and of ‘justification by faith’ (which emphasised the presence of religious consciousness in ‘works’) have a practical rather than a theological significance. The former reflected the notion of ‘self-sacrifice,’ involved in the achievement of self-realisation--where one had to ‘die’ to the desires of one's ‘private will’ in order to ‘live’ as a more complete moral agent. And the latter doctrine was a reminder that one's actions could have a moral and spiritual character only so far as they were carried out, out of a set of dominant ideas to which one was committed.

Bosanquet holds that religion is reasonable, and that any rational person would be religious. He insists that religious belief as a whole is not superstition, and that it is true so far as it is an expression of a ‘nisus to totality’ or a ‘move to wholeness.’ Again, since particular religious beliefs purport to be cognitive, they must, at least in principle, be able to be known by believers and non-believers alike. (He is, however, sceptical about the relevance of traditional apologetics.) In both cases, the standard that Bosanquet employs in order to assess truth in religion is the same as that which he uses to assess the truth in general--namely, coherence.

Though Bosanquet's analysis of religious belief reflects an understanding that, broadly speaking, was shared by a number of his fellow idealists, it is significantly different from other late 19th century and early 20th century perspectives, such as those of William Clifford, John Henry Newman, and William James, and can be seen as an alternative to them. Given its immanentist character and insistence on separating religion from dogma and theology, it is close to the view of religion that one finds in recent work by R.B. Braithwaite, R.M. Hare, W. Cantwell Smith, D.Z. Phillips, and Hendrik Hart, and there is some similarity to the contemporary ‘Sea of Faith’ movement, advanced by the Anglican theologian, Don Cupitt. Bosanquet's views, like those of these authors, have been challenged (for example, by C.C.J. Webb, François Houang, and Alan P.F. Sell) for not only being inconsistent with any orthodox theism, but as presenting in its stead a ‘generic religion’ (which, some critics hold, is not religion at all). It is, however, important to recognise that Bosanquet is not advancing a non-cognitivist or fideist view of religion, and that he maintains that both religious beliefs as a whole and particular religious beliefs must meet appropriate ‘rational’ standards.

Social and Political Philosophy

Bosanquet's social and political philosophy is called ‘idealist’ because of his view that social relations and institutions were not ultimately material phenomena, but best understood as existing at the level of human consciousness. Writing largely in reaction to the utilitarianism of Bentham and Mill and to the natural-rights based theory of Herbert Spencer, Bosanquet's views show both a strong influence of Hegel and an important debt to Kant and to the classical Greek thought of Plato and Aristotle. Indeed, Bosanquet often spoke of his political theory as reflecting principles found in ‘classical philosophy,’ and one of his early works was a commentary on Plato's Republic. Nevertheless, his political thought lies clearly within the tradition of liberalism.

The main source for Bosanquet's social and political philosophy is *The Philosophical Theory of the State* (1899; 4th ed., 1923), though many of his ideas are developed in dozens of articles and essays which he wrote for professional academic journals, for publications of the Charity Organisation Society and for the popular press. Like many of his fellow idealists (notably T.H. Green, D.G. Ritchie, William Wallace, John Watson and, to a lesser degree, F.H. Bradley). Bosanquet's principal concern was to explain the basis of political authority and the state, the place of the citizen in society, and the nature, source and limits of human rights. The political theory that he develops is importantly related to his metaphysics and logic--particularly to such notions as the individual, the general will, ‘the best life’, society, and the state. In order to provide a coherent account of such issues, Bosanquet argued, one must abandon some of the

assumptions of the liberal tradition--particularly those that reveal a commitment to ‘individualism’.

Bosanquet saw authority and the state neither as based on individual consent or a social contract, nor as simply institutions where there is a general recognition of a sovereign, but as products of the natural development of human life, and as expressions of what he called the ‘real’ or general will. On Bosanquet's view, the will of the individual is "a mental system" whose parts--"ideas or groups of ideas"--are "connected in various degrees, and more or less subordinated to some dominant ideas which, as a rule, dictate the place and importance of the others" (i.e., of the other ideas that one has). Thus, Bosanquet writes that, "[i]n order to obtain a full statement of what we will, what we want at any moment must at least be corrected and amended by what we want at all other moments." But the process does not stop there. He continues: "this cannot be done without also correcting and amending it so as to harmonise it with what others want, which involves an application of the same process to them." In other words, if we wish to arrive at an accurate statement of what our will is, we must be concerned not only with what we wish at some particular moment, but also with all of the other wants, purposes, associations and feelings that we and others have (or might have) given all of the knowledge available. The result is one's ‘real’ or the ‘general will’.

Bosanquet sees a relation between the ‘real’ or ‘general will’ and the ‘common good.’ He writes that "The General Will seems to be, in the last resort, the ineradicable impulse of an intelligent being to a good extending beyond itself." This ‘good’ is nothing other than "the existence and the perfection of human personality" which he identifies with "the excellence of souls" and the complete realisation of the individual. It is so far as the state reflects the general will and this common good that its authority is legitimate and its action morally justifiable. Bosanquet describes the function of the state, then, as ‘the hindrance of hindrances’ to human development.

The influence of Rousseau and Hegel is clearly evident here. Indeed, Bosanquet saw in Hegel's *Philosophy of Right* a plausible account of the modern state as an ‘organism’ or whole united around a shared understanding of the good. Moreover, like Hegel, he argued that the state, like all other social ‘institutions,’ was best understood as an ethical idea and as existing at the level of consciousness rather than just material reality. Within nation states, Bosanquet held that the authority of the state is absolute, because social life requires a consistent co-ordination of the activities of individuals and institutions.

Still, although Bosanquet believed that the state was absolute, he did not exclude the possibility of an organized system of international law. The conditions for an effective recognition and enforcement of such a system were, he thought, absent at that moment--though he held out hope that the League of Nations reflected the beginnings of the consciousness of a genuine human community and that it might provide a mechanism by which multinational action could be accomplished.

Because the state can be said to reflect the general will that is also each individual's real will, Bosanquet held (following Rousseau) that sometimes individuals can be required to engage in certain activities for their own good--that is they can be ‘forced to be free.’ Moreover, he maintained that it is in terms of the ‘common good’ that one's ‘station’ or ‘function’ in society is defined, and it is the conscientious carrying out of the duties that are attached to one's ‘station’ that constitutes ethical behaviour. In fact, on

Bosanquet's account, it is primarily in light of one's service in the state that a person has the basis for speaking of his or her particular identity. Not surprisingly, then, Bosanquet was frequently challenged by those who claimed that he was anti-democratic and that his philosophical views led to a devaluation of the individual. Such attacks ignore, however, Bosanquet's insistence on liberty as the essence and quality of the human person and his emphasis on the moral development of the human individual and on limiting the state from directly promoting morality (which reflects both his own reading of Kant and the influence of Green's Kantianism.) Moreover, while Bosanquet did not hold that there were any *a priori* restrictions on state action, he held that there were a number of practical conditions that did limit it. For example, while law was seen as necessary to the promotion of the common good, it could not make a person good, and social progress could often be better achieved by volunteer action. (It is just this emphasis that Bosanquet found and defended in the approach to social work of the Charity Organisation Society.)

Although the state and law employ compulsion and restraint, they were considered to be ‘positive’ in that they provided the material conditions for liberty, the functioning of social institutions, and the development of individual moral character. For Bosanquet, then, there was no incompatibility between liberty and the law. Moreover, since individuals are necessarily social beings, their rights were neither absolute and inalienable, but reflected the ‘function’ or ‘positions’ they held in the community. For such rights to have not only moral but legal weight, Bosanquet insisted that they had to be ‘recognized’ by the state in law. Strictly speaking, then, there could be no rights against the state. Nevertheless, Bosanquet acknowledged that, where social institutions were fundamentally corrupt, even though there was no right to rebellion, there could be a duty to resist.

Although Bosanquet is sometimes regarded as a conservative, recent studies have pointed out that he was an active Liberal and, in the 1910s, supported the Labour Party. He insisted on the positive role that the state can have in the promotion of social well being and he was in favour of worker ownership. It is also worth noting that Bosanquet's audience was as much the professional in social work or the politician, as the philosopher. He was well-informed of the political situation in Britain, on the continent, and in the United States. His interests extended to economics and social welfare, and his work in adult education and social work provides a strong empirical dimension to his work. This background provided him with a broad base from which to reply to challenges from many of his critics-- e.g., from philosophers, like Mill and Spencer, and from social reformers, such as Sidney and Beatrice Webb and, the founder of the Salvation Army, General William Booth. Despite charges that Bosanquet's political philosophy is simplistic, inconsistent, or naive, Adam Ulam notes that *The Philosophical Theory of the State* "has a comprehensiveness and an awareness of conflicting political and philosophical opinions which give it a supreme importance in modern political thought. Bosanquet is both a political theorist and a political analyst."

It has sometimes been suggested that the influences of Kant and Hegel lead to a tension in Bosanquet's political thought. Bosanquet's emphasis on the moral development of the human individual and on limiting the state from directly promoting morality clearly reflects both his own reading of Kant and the Kantian influences on Green. Moreover, Bosanquet believed that the ‘best life’ that he describes as the ‘end’ of the individual and of the state alike, approximates what Kant referred to as ‘the kingdom of ends’. Even Bosanquet's justification of the authority of the state can be seen as a reflection of a Kantian

imperative that one wills the state as a necessary means to the moral end.

General Assessment

Interest in Bosanquet's work--as with idealism as a whole--waned during the middle decades of the 20th century. Of the idealists, the writings of Bradley and, in political theory, Green, are now much better known. There is no simple explanation of this; many factors seem relevant.

First, some of the work that made Bosanquet's reputation in his time--his popular essays, the books and articles that came out of his university extension courses, and his involvement in social policy--now seems largely dated. For example, several of his essays lack the logical rigor that one finds in material destined for the more specialized audience of academic philosophers. While insightful and wide ranging--and while accessible to a much wider audience than the work of other idealists, such as Bradley and J.M.E. McTaggart--Bosanquet's writings lack the sharpness, the density, and, at times, the outrageousness of those of some of his contemporaries.

It has been suggested, as well, that some of the concepts central to Bosanquet's work are not clearly defined, and Bosanquet himself was an indifferent literary stylist. His work often betrays a looseness that one tends to find in texts based on lectures prepared for general audiences or for classes, and even his early work on logic was remarked upon for its "stiffness." But these primarily stylistic concerns may also be a product of refusing to sever the analysis of concepts from the experience which Bosanquet was trying to describe.

There are other reasons that no doubt contributed to the decline of interest in Bosanquet's work. Aside from the general collapse of idealism as a philosophical movement--by the early part of the 20th century, it was seen by many as a philosophical dead- end--and the suspicion of what was regarded by later generations as its obscure vocabulary, Bosanquet's association with the majority report of the Poor Law Reform Commission and his alleged championing of the nation state, led many to see him as a conservative if not reactionary thinker whose contributions to philosophy and politics were outdated almost as soon as they had been published.

In recent years, however, there has been a renewed interest in Bosanquet's work--particularly concerning his philosophical and social thought, which is experiencing a revival in the work of some contemporary liberal theorists. Given the number of studies published during the past twenty years on Hegel, Green and, more recently, Bradley, and given the reevaluation of the significance of the work of British idealism and its place in the history of philosophy, it seems likely that there will be a reconsideration of the contribution of Bosanquet's philosophy as well.

Bosanquet's Works

A Comprehensive Listing:

The most comprehensive list to date of Bosanquet's work is found in Peter P. Nicholson, "A Bibliography of the Writings of Bernard Bosanquet (1848-1923)," *Idealistic Studies*, 8 (1978): 261-280.

Principal Works

The publication of a 20 volume set of *The Works of Bernard Bosanquet* (edited by William Sweet) is planned by Thoemmes Press (Bristol, U.K.) for 1999. This will include the following principal works:

- *Knowledge and Reality, A Criticism of Mr. F. H. Bradley's 'Principles of Logic'*. London: Kegan Paul, Trench, 1885.
- *Logic, or the Morphology of Knowledge*. Oxford: Clarendon Press, 1888. 2d ed., 1911.
- *Essays and Addresses*. London, Swan Sonnenschein, 1889.
- *A History of Aesthetic*, London: Swan Sonnenschein, 1892. 2d ed., 1904.
- *The Civilization of Christendom and Other Studies.* London: Swan Sonnenschein, 1893.
- *The Essentials of Logic: Being Ten Lectures on Judgement and Inference*. London and New York: Macmillan, 1895.
- *Aspects of the Social Problem*, London, 1895.
- *A Companion to Plato's Republic for English Readers: Being a Commentary adapted to Davies and Vaughan's Translation*. New York/London, 1895.
- *The Philosophical Theory of the State*, London, 1899; 4th ed., 1923.
- *Psychology of the Moral Self*, London and New York: Macmillan, 1897.
- *The Principle of Individuality and Value. The Gifford Lectures for 1911 delivered in Edinburgh University*. London: Macmillan, 1912.
- *The Value and Destiny of the Individual. The Gifford Lectures for 1912 delivered in Edinburgh University*. London: Macmillan, 1913.
- *The Distinction Between Mind and its Objects. The Adamson Lecture for 1913 with an Appendix.* Manchester: University Press, 1913
- *Three Lectures on Aesthetic*, London: Macmillan, 1915.
- *Social and International Ideals: Being Studies in Patriotism*, London: Macmillan, 1917.
- *Some Suggestions in Ethics*, London: Macmillan, 1918; 2nd ed. 1919.
- "Do Finite Individuals possess a substantive or an adjectival mode of being?", *Life and Finite Individuality*, (ed. H. Wildon Carr), *Proceedings of the Aristotelian Society*, supp. vol. 1, (1918): 75-102; 179-194 (Reprinted from *Proceedings of the Aristotelian Society*, n.s. XVIII (1917-1918): 479-506.)
- *Implication and Linear Inference*, London: Macmillan, 1920.
- *What Religion Is*, London: Macmillan, 1920.
- *The Meeting of Extremes in Contemporary Philosophy*. London: Macmillan, 1921.
- *Three Chapters on the Nature of Mind*, London: Macmillan, 1923.
- "Life and Philosophy," *Contemporary British Philosophy*, (ed. J.H. Muirhead), London, 1924, pp. 51-74.
- *Science and Philosophy and Other Essays by the Late Bernard Bosanquet*, (ed. J.H. Muirhead and

R.C. Bosanquet), London, Allen and Unwin, 1927.

The Revision Theory of Truth

The revision theory of truth was developed independently by Gupta (1982) and Herzberger (1982) in an attempt to analyze paradoxes such as the liar paradox that appear to show that common-sense beliefs about truth are inconsistent.

Liar Paradox

Consider the following "liar sentence."

(L) Sentence (L) is not true.

Sentence (L) says of itself that it is not true. A contradiction can be derived from (L) from apparently trivial principles. One basic intuition about truth needed is that a sentence is true if and only if what it asserts is the case. For example, the sentence "there is gold on the moon" is true if and only if there is gold on the moon. Applying this principle in the particular case of sentence (L) results in:

(1) Sentence (L) is true if and only if sentence (L) is not true.

Notice that sentence (L) asserts precisely that it is not true. So by the principle just mentioned it is true if and only if it is not true.

Another principle needed to obtain an explicit contradiction is the following:

(2) Sentence (L) is either true or not.

Sentence (1) may already appear to be obviously contradictory. If not, a contradiction can be quickly derived using (2) by breaking into the two cases it allows: that (L) is true, or that (L) is not.

Case 1. Sentence (L) is true. Then by (1) sentence (L) is not true. So it is both true and not true, which is impossible.

Case 2. Sentence (L) is not true. Then by (1) sentence (L) is true. Again it is both true and not true, which is impossible.

So either of the two cases is seen to be impossible by applying (1). This seems to imply that at least one of these basic intuitions expressed in (1) and (2) is wrong.

Description of the Theory

The revision theory of truth seeks to explain the meaning of truth. According to the theory the meaning of truth for a collection of sentences (a "language") is given by the "Tarski biconditionals" as they are called in Gupta (1982). An example of a Tarski biconditional is (1) above. In general, where P is a sentence of the language and S is a name of the sentence, the Tarski biconditional for the sentence is:

> S is true if and only if P

One way of forming names of sentences is by quotation, so that if the sentence in question is "there is gold on the moon," the Tarski biconditional for the sentence is:

> "there is gold on the moon" is true if and only if there is gold on the moon.

Another method of giving names to sentences is by Goedel numbering, assigning numbers to sentences in some typically systematic fashion.

While the Tarski biconditionals seem to be quite trivial, they are seen to lead to blatant contradictions when applied to sentences such as the liar sentence.

According to the revision theory, while the Tarski biconditionals give the meaning of truth, special semantical tools are needed to show how they generate the concept of truth. In particular, the theory accepts that truth is a circular concept, and provides special tools for understanding circular concepts such as truth. Thus, the reasoning above that resulted in a contradiction from would be seen as misapplying the information expressed in (1), the Tarski biconditional for the liar sentence.

On the revision theory, Tarski biconditionals such as (1) should be understood as having a hypothetical character. While they entirely define the concept of truth, they do so only in virtue of the special role

given to them by the revision theory. In particular, the biconditionals are seen as providing a method for obtaining better and better approximations of the extension of the truth predicate. Thus, they do not simply provide the extension of the truth predicate, but provide an improvement on any temporary extension that might be suggested.

Thus, let M be an ordinary first-order model that also gives an arbitrary extension to the truth predicate. The Tarski biconditionals provide a method for obtaining an improved model M*. Namely, for any sentence P having name S, S is assigned to the extension of the truth predicate in M* if P evaluates as true in M, and not assigned to the extension of truth otherwise. Thus, given any model M with any initial extension to the truth predicate, the biconditionals generate a series of models M*, M**, M***, etc., that are constructed using the biconditionals by evaluating sentences in the previous member of the series.

The series is also extended into the transfinite by collecting together the results from earlier stages at limit ordinals. One method of doing this is, at a limit stage, letting the extension of truth at the limit stage consist of all (names of) sentences that have stabilized as the sequence approached the limit. That is, if at some stage in the sequence a sentence is declared true at every subsequent stage below the limit stage, then put it in the extension of truth at the limit. Many other reasonable limit rules are possible here.

Consequences and Properties

A "revision sequence" is any sequence of models beginning with an arbitrary model M that is generated by the Tarski bicondionals according to the revision theory of truth.

Some sentences will stabilize eventually in every revision sequence. For example, where "T" is the truth predicate, let S be the name of the sentence "T(T(F(b)))" where "F" is an arbitrary one-place predicate and "b" is an arbitrary name.

Let M(T) represent the extension assigned to T by M. Then S is in M**(T) if and only if "T(F(b))" is in M*(T). But "T(F(b))" is in M*(T) if and only if "F(b)" is in M(T). Thus, S is in M**(T) if and only if "F(b)" is in M(T), that is, if and only if b is in M(F). Likewise, from the second revision onwards, S is assigned to the extension of truth if and only if b is in the extension of the predicate F. So beginning with any model M the sentence S stabilizes as either true or false in every revision sequence depending on whether "F(b)" is evaluated as either true or false in the original model M.

Intuitively "normal" sentences stabilize in every sequence. Sentences such as the liar sentence exhibit unusual behavior in the framework of the revision theory. For example, the liar sentence alternates between true and false at successive revisions in every revision sequence. Hence it exhibits extremely unstable behavior.

Many other classifications of sentences with respect to their behavior over various revision sequences are possible. Some will stabilize as false in all sequences. Some will stabilize as true in some but not all sequences. Some will stabilize as true in some sequences and false in the rest. This apparatus provides

tools for fine-grained classifications of various types of sentences into different semantical categories.

Because the theory deals with sequences of classical models, every logical truth will stabilize as true in every sequence and every logical falsehood as false in every sequence. Hence one of the advantages often claimed for the revision theory is that it supports classical reasoning in contrast to various other approaches to truth.

Along with other recent theories of truth, the revision theory has the feature that given any revision, eventually a stage will be reached at which every sentence that will ever stabilize as true or as false in the sequence has already stabilized.

Folk Psychology as a Theory

Many philosophers and cognitive scientists claim that our everyday or "folk" understanding of mental states constitutes a theory of mind. That theory is widely called "folk psychology" (sometimes "commonsense" psychology). The terms in which folk psychology is couched are the familiar ones of "belief" and "desire", "hunger", "pain" and so forth. According to many theorists, folk psychology plays a central role in our capacity to predict and explain the behavior of ourselves and others. However, the nature and status of folk psychology remains controversial.

Historical Background

One important source of the idea that our everyday understanding of mental states constitutes a folk theory of mind is Wilfred Sellars's attack on what he called "the myth of the given" (Sellars 1956). Sellars denied that the content of our mental life is simply presented to us; that is, he denied that our beliefs about our own mental states enjoy a privileged epistemic status. To weaken the grip of the myth of the given he presented an alternative myth in which our ancestors, initially limited to a purely behavioristic understanding of action, learned a new theory of action that posits inner episodes as the causes of overt behavior. At first our ancestors only applied the new theory to others, but then they learned to "read" their own mental states off their behavior. In the final stages of the myth they became adept at mental state self-attribution without theorizing from their behavior; nevertheless the self-attributed states remain the posits of an introduced theory of mind.

It need hardly be said that Sellars did not take himself to have accurately accounted for the historical

origins of our capacity for mental state attribution. Rather, his aim was to open a new space in the debate about the status of mental state attributions by pointing out that mental states could be the posits of a theory of mind. As we shall see, subsequent generations took Sellars's suggestion entirely seriously, and were right to do so.

Another important historical source of the idea that our everyday understanding of mental states constitutes a folk theory of mind is the rise of cognitivism in the 1960s. Following the widespread perception that behaviorism had failed, cognitive scientists began to posit internal episodes as causes of overt behavior. These internal episodes were typically taken to be *representations,* and the term "theory" was applied to posited representational structures of sufficient complexity. For example, cognitive scientists seeking to explain our capacity to manipulate middle-sized physical objects posited an internally represented theory of dynamics, often referred to as "folk physics". (See for example McCloskey 1983.) It was only natural, therefore, that cognitive scientists adopted the explanatory strategy of positing internally represented theories when they attempted to explain our folk capacity to predict and explain behavior. The label "folk psychology" was widely adopted for that posit.

It is worth mentioning a third historical strand. Since at least the 1940s social psychologists have been interested in our capacity to attribute mental states to others. In an important early study, Heider and Simmel showed subjects a short movie which consisted of geometric shapes moving on a screen (Heider & Simmel 1944). When asked to report what they saw, almost every subject attributed propositional attitudes to the shapes, suggesting the existence of a universal and largely automatic capacity for propositional attitude attribution. In subsequent decades, social psychologists explored the accuracy and limitations of this capacity. For example, Nisbett and Wilson (1977) investigated a range of circumstances under which subjects *mispredict* behavior, and discovered that the circumstances under which mispredictions occur are just those circumstances under which subjects offer contrived or confabulated explanations of behavior.

Two Senses of "Folk Psychology"

I remarked above that many philosophers and cognitive scientists claim that our folk understanding of mental states constitutes a theory of mind. But we can unpack the idea of an *understanding* of mental states in two ways, yielding two different senses of "folk psychology": an *externalist* sense and an *internalist* sense (Stich & Ravenscroft 1994).

On the externalist account of folk psychology, folk psychology is a theory of mind implicit in our everyday talk about mental states. In the everyday traffic of our lives we make remarks linking sensory experiences to mental states; mental states to other mental states; and mental states to behavior. Thus we remark that the smell of freshly baked bread made Sally feel hungry; that Sally wanted to go on a diet because she thought that she was overweight; and that Sally went to the fridge because she desired a piece of chocolate cake. According to some philosophers, remarks such as these (or suitable generalisations of remarks such as these) function as a term-introducing theory which implicitly defines terms such as "believe", "want" and "desire". (See for example Lewis 1972.)

On the internalist account of folk psychology, folk psychology is a theory of human psychology which is represented in the mind-brain and which underpins our everyday capacity to predict and explain the behavior of ourselves and others. On this view, folk psychology is a *data structure* or *knowledge representation* which mediates between our observations of behavior-in-circumstances and our predictions and explanations of that behavior.

In the following two sections I give further details about the externalist and internalist accounts of folk psychology, respectively. In the final section I raise some issues about the relationship between folk psychology (internal) and folk psychology (external). However, before moving on it will be helpful to introduce a further piece of terminology which is often used in the literature.

The claim that our everyday understanding of mental states constitutes a folk theory of mind is often called the "theory theory". We have seen that two senses of "folk psychology" can be distinguished; similarly, two senses of "theory theory" can be distinguished. On the *externalist* reading of "theory theory", our everyday talk about mental states implicitly constitutes a theory of mind: folk psychology (external). On the *internalist* reading of "theory theory", our everyday capacity to predict and explain behavior is underpinned by an internally represented theory of mind: folk psychology (internal). Unfortunately, theory theorists are not always as clear as one might hope about which sense of "theory theory" they are endorsing.

The Nature and Status of Folk Psychology (External)

The principal architect of theory theory (external) is David Lewis (see especially Lewis 1972). Lewis instructs us to:

> Collect all the platitudes ... regarding the causal relations of mental states, sensory stimuli, and motor responses. ... Add also all the platitudes to the effect that one mental state falls under another ... Perhaps there are platitudes of other forms as well. Include only the platitudes which are common knowledge amongst us: everyone knows them, everyone knows that everyone else knows them, and so on. (Lewis 1972: 256.)

Having assembled the platitudes we can then form their conjunction. Let $m_1, \ldots, m_n$ be the mental state terms used in these platitudes. We can then express the conjunction of platitudes as:

$$S_1(m_1, \ldots ,m_n) \ \& \ S_2(m_1, \ldots ,m_n) \ \& \ \ldots \ \& \ S_j(m_1, \ldots ,m_n)$$

where each $S_i(m_1, \ldots ,m_n)$ is a sentence in which some or all of the mental state terms m_i occur. This conjunction will also contain a variety of terms which name non-mental states. For example, it will

contain terms referring to types of sensory input (sharp blows; bright lights; gentle strokings) and to types of behavioral output (saying "ouch"; shielding the eyes; smiling). Following Lewis we can call these terms the *O-terms* ($O_1, \dots, O_n$). In the interests of clarity, these terms have been suppressed.

We can now replace (each occurrence of) mental state term m_i by a corresponding free variable x_i:

$$S_1(x_1, \dots ,x_n) \ \& \ S_2(x_1, \dots ,x_n) \ \& \ \dots \ \& \ S_j(x_1, \dots ,x_n)$$

Prefixing an existential quantifier we obtain the *Ramsey sentence* for folk psychology:

$$\exists x_1 \dots x_n[S_1(x_1, \dots ,x_n) \ \& \ S_2(x_1, \dots ,x_n) \ \& \ \dots \ \& \ S_j(x_1, \dots ,x_n)]$$

The Ramsey sentence for folk psychology says that there exists a set of entities $x_1, \dots ,x_n$ which exhibit just those relations which the states named by the term $m_1, \dots , m_n$ exhibit. It is possible to obtain from the Ramsey sentence an explicit definition of any mental state term m_i. (See Lewis 1972 for the formal details.) Lewis has thus shown how to obtain an explicit definition of any mental state term m_i from the collected platitudes; in other words, he has shown how we can treat our everyday talk about mental states as a term-introducing theory of mind.

To clarify Lewis's Ramsey sentence approach, assume that our everyday talk about mental states consists of just three platitudes:

P1 Bodily damage causes pain.

P2 People who are in pain experience acute distress.

P3 People who are in pain nurse the afflicted body part.

These platitudes express the causal relationships between bodily damage and pain; between pain and states of acute distress; and between pain and a certain sort of behavior (nursing the afflicted body part).

Using "m_1" for "pain" and "m_2" for "acute distress", we can write the conjunction of P1 to P3 as:

$$S_1(m_1) \ \& \ S_2(m_1, m_2) \ \& \ S_3(m_1)$$

Once again the O-terms have been suppressed in the interests of clarity, but it is worth bearing in mind that the O-terms include a name referring to bodily damage and a name referring to a certain sort of behavior, *viz*, nursing the afflicted body part.

Replacing m_1 and m_2 with free variables x_1 and x_2, respectively, we obtain:

$$S_1(x_1) \& S_2(x_1, x_2) \& S_3(x_1).$$

Prefixing an existential quantifier we obtain the Ramsey sentence for our toy theory:

$$\exists x_1, x_2[S_1(x_1) \& S_2(x_1, x_2) \& S_3(x_1)].$$

The Ramsey sentence says that there exists states x_1 and x_2 that (respectively) play the roles accorded to pain and acute distress by the platitudes P1 to P3.

From the Ramsey sentence we can obtain an explicit definition of, say, m_1. (Again readers are encouraged to consult Lewis 1972 for the formal details.)

> m_1 (ie pain) = the unique x_1 such that x_1 is caused by bodily damage, causes acute distress, and causes the nursing of the afflicted body part.

Notice that the definition of m_1 was obtained from the platitudes: nothing was added during the process of defining m_1. It is clear, therefore, that the definition was implicit in the platitudes all along.

This example makes it clear that Lewis is primarily concerned with those platitudes which detail "the causal relations of mental states, sensory stimuli, and motor responses" (Lewis 1972: 256). Lewis is therefore interpreting folk psychology as a *functionalist* theory; that is, as a theory which identifies mental states in terms of their causal-functional relations. Indeed, some authors use the terms "theory theory" and "functionalism" interchangeably. Attractive though Lewis's position is, it is at least partly hostage to fortune. For it is an open question whether the theory implicit in our everyday platitudes about mental states really is a strictly functionalist one. Many authors have doubted that, for example, our talk about qualia can be adequately cashed out in functionalist terms. (See for example Chalmers 1996.) Indeed, it is an open question whether our everyday talk about mental states is sufficiently systematic to support Lewis's Ramsey sentence approach.

There is, moreover, a largely empirical question to be raised about folk psychology (external). For even if we accept that our everyday talk about mental states implicitly constitutes a theory of mind, it remains to be determined if that theory is *true*. Maybe future research in psychology or neuroscience will establish that folk psychology (external) is false. And if folk psychology (external) is false, it would seem to follow that there are no such thing as beliefs and desires, pains, hungers and tickles. This surprising doctrine is called *eliminativism*, and has been a major focus of discussion amongst philosophers of mind over the last 15 years. (See Churchland 1981; Horgan & Woodward 1985.)

The Nature and Status of Folk Psychology (Internal)

In our everyday social interactions we both predict and explain behavior, and our explanations are couched in a mentalistic vocabulary which includes terms like "belief" and "desire". For brevity's sake we can refer to such activities as *mentalizing*, and we can ask about the cognitive mechanisms which underpin our capacity to mentalize. According to the theory theory (internal), our capacity for mentalization crucially involves an internally represented theory of mind: folk psychology (internal). On this view, predicting and explaining human behavior is akin to predicting and explaining the movements of the heavenly bodies using Newton's mechanics. As we shall see, this analogy is very rough, but it emphasizes the central place given to theorizing on the theory theory model.

It is important to stress that internalist theory theorists need not be committed to any particular theory of mental representation. In particular, they need not be committed to the language of thought hypothesis. Folk psychology (internal) may be represented in the language of thought, or by a distributed connectionist network, or by some other means. (This point is well made by Stich & Nichols 1992.) Of course, since theories are essentially *representational* structures, theory theory (internal) is incompatible with radically *anti-representationalist* theories of mind. I will not, though, consider anti-representationalism further.

It is also important to stress that internalist theory theorists need not be committed to the claim that folk psychology (internal) is learned in the way that we learn, say, physics or chemistry. (It is here that the analogy with Newtonian mechanics breaks down.) Some internalist theory theorists have argued that folk psychology is indeed largely learned (see Gopnik & Wellman 1992). That position has been challenged by a version of Chomsky's "poverty of stimulus" argument. Empirical studies suggest that young children become fairly competent folk psychologists by four or five years (Wimmer & Perner 1983). Is it really plausible that four year olds have been exposed to sufficient examples of behavior-in-circumstance to construct, via the principles of induction, full-blown folk psychology?

Other internalist theory theorist argue that folk psychology (internal) is largely innate; or at least that we are born with a mechanism dedicated to the acquisition of folk psychology (see for example Fodor 1992 and Carruthers 1996: especially Section 1.7). There are strong parallels here with debates about nativism in psycholinguistics. Some psycholinguists argue that our capacity to use language is a product of natural selection (see for example Pinker 1994). Similarly, some internalist theory theorists argue that our capacity to predict and explain behavior is a product of natural selection (see for example Baron-Cohen 1992).

It should be clear that the theory theory (internal) is a very attractive doctrine. Nevertheless, it has not remained unchallenged. Simulation theorists have argued that our mentalizing capacity is not primarily a capacity to theorize but is rather a capacity to *simulate* the mental processes of others. (See folk psychology, as simulation.) The debate between simulationists and internalist theory theorists has both philosophical and empirical dimensions, and it is fair to say that, at present, the issue is very much open. (For an excellent introduction to this debate see Davies & Stone 1995.)

Concluding Remarks

I have identified two distinct senses of "folk psychology". What is the relationship between the theories to which those terms refer? It is implausible that the theory of mind implicit in our everyday talk about mental states is simply identical to the internally represented theory of mind which underpins our capacity to mentalize. Rather, it is likely that folk psychology (internal) is partly inaccessible to consciousness, and that folk psychology (external) is an articulation of that fragment of folk psychology (internal) which is available to conscious reflection. It follows that our everyday talk about the mind is only a rough guide to folk psychology (internal).

The previous paragraph assumed that the theory theory is true on both its internalist and its externalist readings. But if simulation theory is true, our capacity to mentalize is not underpinned by folk psychology (internal) and so the internalist version of the theory theory is false. Note, though, that the externalist version of the theory theory could remain true *even if* the internalist version were false: simulation theory is compatible with the idea that our everyday talk about mental states implicitly constitutes a theory of mind. These options, and the consequences for eliminativism, are considered in more detail in Stich & Ravenscroft 1994.

Folk Psychology as Mental Simulation

The simulation (or, "mental simulation") theory maintains that human beings are able to use the resources of their own minds to simulate the psychological causes of the behavior of others, typically by making decisions within a "pretend" context. The theory is usually, though not always, taken to present a serious challenge to the assumption that a *theory* underlies everyday human competence in predicting and explaining behavior, including the capacity to ascribe mental states to others. Unlike earlier controversies concerning the role of empathetic understanding and historical reenactment in the human sciences, the current debate between the simulation theory and the "theory" theory appeals to empirical findings, particularly experimental results concerning children's development of psychological competence. These are detailed in what follows.

What is Meant by ‘Simulation’?

Like the term ‘theory,’ ‘simulation’ has come to be used broadly and in a variety of ways. Simulation is sometimes equated with role-taking, or "putting oneself in the other's place." However, it is often taken to include mere "projection," or reliance on a shared world of facts and emotive and motivational charges, without adjustments in imagination; e.g., where there is no need to *put* oneself in the other's place, as one is, in all relevant respects, already there. (Gordon calls this the default mode of simulation.) Sometimes it is taken to include as well automatic responses such as the subliminal mimicry of facial expressions and bodily movements. Stephen Stich and Shaun Nichols, whose critical papers have clarified the issues and helped refine the theory, urge that the term be dropped in favor of a finer-grained terminology.

Simulation is often conceived in cognitive-scientific terms: one's own behavior control system is

employed as a manipulable model of other such systems. The system is first taken off-line, so that the output is not actual behavior but only predictions or anticipations of behavior, and inputs and system parameters are accordingly not limited to those that would regulate one's own behavior. Many proponents hold that, because one human behavior control system is being used to model others, general information about such systems is unnecessary. The simulation is thus said to be process-driven rather than theory-driven (Goldman).

The simulation theory is often thought to require that, to anticipate or to explain another's behavior, one has to make decisions in the role of the other--something we are not frequently aware of doing. However, decision-making, insofar as it results in a decision to perform a definite action, would always yield a definite prediction. Something short of decision-making would better account for our actual capacity to anticipate behavior, limited as it is. For people commonly allow a range of indeterminacy in their expectations of what others will do: some actions are seen as unsurprising given the person and the situation, and others as very surprising. Even if one does not make a decision in the role of the other, one can, by making adjustments in imagination, make some possible actions appear attractive (and thus unsurprising) and others unattractive (and thus surprising).

Varieties of Simulation Theory

Alvin Goldman and the psychologist Paul Harris conceive simulation differently from Robert Gordon and Jane Heal, the philosophers who, working independently, introduced the theory in 1986. According to Goldman and (less clearly) Harris, to ascribe mental states to others by simulation, one must already be able to ascribe mental states to oneself by introspection, and thus must already possess the relevant mental state concepts. Gordon holds a contrary view suggested by both Kant and Quine: Only those who can simulate can understand an ascription of, e.g., belief--that *to S* it is the case that p. While no simulation theorist claims that all our everyday explanations and predictions of the actions of other people are based on role-taking, Heal in particular has been a moderating influence, arguing for a hybrid simulation-and-theory account that reserves simulation primarily for items with rationally linked content, such as beliefs, desires, and actions.

The introspectionist account of simulation may suggest that simulation is just an application of the argument from analogy. According to one version of this argument,

> I am conscious in myself of a series of facts connected by an uniform sequence, of which the beginning is modifications of my body, the middle is feelings, the end is outward demeanour. In the case of other human beings I have the evidence of my senses for the first and last links of the series, but not for the intermediate link....by supposing the link to be of the same nature as in the case of which I have experience,...I bring other human beings, as phenomena, under the same generalizations which I know by experience to be the true theory of my own existence. -- J.S. Mill, *An Examination of Sir William Hamilton's Philosophy*. 6th edition. London, 1869.

Likewise, the "one system modeling another"account may suggest that simulation is a device for discerning what goes on "inside" another, based on an assumption of the internal similarity of the simulating system and the target system. However, where one explains or predicts another's behavior in terms of a shared, jointly known world, there is no question of internal resemblance between simulator and target, only one of *what it is about the world* that moves the other to action. What is presumed is not similarity but access, not that the other believes as one does but that the other has access to (what one presumes to be) the world.

Areas of Empirical Investigation

Three main areas of empirical investigation have been thought especially relevant to the debate:

- ***False belief.*** Taking into account another's ignorance or false belief when predicting or explaining their behavior requires imaginative modifications of one's own beliefs, according to the simulation theory. Thus the theory offers an explanation of the results of numerous experiments showing that younger children fail to take such factors into account. It would also explain the correlation, in autism, of failure to take into account ignorance or false belief and failure to engage in spontaneous pretend-play, particularly role play. Although these results can also be explained by certain versions of theory theory (and were so interpreted by the experimenters themselves), the simulation theory offers a new interpretation.
- ***Priority of self- or other-ascription.*** A second area of developmental research asks whether children ascribe mental states to themselves before they ascribe them to others. Versions of the simulation theory committed to the view that we recognize our own mental states as such and make analogical inferences to others' mental states seem to require an affirmative answer to this question; other versions of the theory seem to require a negative answer. Some experiments suggest a negative answer, but debate continues on this question.
- ***Cognitive impenetrability.*** Stich and Nichols suppose simulation to be "cognitively impenetrable" in that it operates independently of any general knowledge the simulator may have about human psychology. Yet they point to results suggesting that when subjects lack certain psychological information, they sometimes make incorrect predictions, and therefore must not be simulating. Because of problems of methodology and interpretation, as noted by a number of philosophers and psychologists, the cogency of this line of criticism is unclear.

The numerous other empirical questions of possible relevance to the debate include the following:

> Does brain imaging reveal that systems and processes employed in decision-making are reemployed in the explanation and prediction of others' behavior?
>
> Does narrative (including film narrative) create emotional and motivational effects by the same processes that create them in real-life situations?

Some philosophers think the simulation theory may shed light on issues in traditional philosophy of mind and language concerning intentionality, referential opacity, broad and narrow content, the nature of mental causation, Twin Earth problems, the problem of other minds, and the peculiarities of self-knowledge. Several philosophers have applied the theory to aesthetics, ethics, and philosophy of the social sciences. Success or failure of these efforts to answer philosophical problems may be considered empirical tests of the theory, in a suitably broad sense of "empirical."

Wilfrid Sellars

Wilfrid Stalker Sellars (b. 1912, d. 1989) was a profoundly creative and synthetic thinker whose work both as a systematic philosopher and as an influential editor helped set and shape the Anglo-American philosophical agenda for over four decades. Sellars is perhaps best known for his classic 1956 essay "Empiricism and the Philosophy of Mind", a comprehensive and sophisticated critique of "the myth of the given" which played a major role in the postwar deconstruction of Cartesianism, but his published corpus of three books and more than one hundred essays includes numerous original contributions to ontology, epistemology, and the philosophies of science, language, and mind, as well as sensitive historical and exegetical studies.

Sellars' Life and Career

- 1912 born May 20 in Ann Arbor, MI
- 1933 receives AB at the University of Michigan
- 1934 receives AM at the University of Buffalo, NY, enters Oriel College, Oxford, as a Rhodes Scholar
- 1936 receives BA with First Class Honours in Philosophy, Politics, and Economics (MA 1940)
- 1938 becomes Assistant Professor of Philosophy, University of Iowa
- 1943 enters U.S. Naval Reserve, assigned to Air Combat Intelligence
- 1946 becomes Assistant Professor of Philosophy, University of Minnesota
- 1950 founds *Philosophical Studies* with Herbert Feigl, the first scholarly forum explicitly created

for the new hybrid "analytic philosophy"
- 1951 becomes Professor of Philosophy, University of Minnesota
- 1956 serves as Special Lecturer in Philosophy at the University of London, published as "Empiricism and the Philosophy of Mind"
- 1958 moves to Yale University, CN, first as a visitor, subsequently as Professor of Philosophy
- 1963 assumes the position of University Professor of Philosophy and Research Professor of Philosophy at the University of Pittsburgh, PA, publishes *Science, Perception and Reality*
- 1965 delivers John Locke Lectures for 1965-66 at Oxford University, subsequently published as *Science and Metaphysics*
- 1970 serves as president of the Eastern Division of the American Philosophical Association
- 1971 delivers Matchette Foundation Lectures, University of Texas, subsequently published as "The Structure of Knowledge"
- 1973 delivers John Dewey Lectures for 1973-74, University of Chicago, IL, subsequently published as *Naturalism and Ontology*
- 1977 delivers Paul Carus Lectures for 1977-78 at the Eastern Division meetings of the American Philosophical Association, later published as "Foundations for a Metaphysics of Pure Process"
- 1987 Colloquium in Sellarsian Philosophy held at University of Pittsburgh in honor of Sellars' 75th birthday
- 1989 dies at home in Pittsburgh, PA, on July 2

Sellars' Metaphilosophy

Although Wilfrid Sellars is best known for his his ground-breaking essay "Empiricism and the Philosophy of Mind" [EPM] and his critique of what he there called "the myth of the given", he was in fact a systematic philosopher *par excellence*. "The aim of philosophy," he wrote, "is to understand how things in the broadest possible sense of the term hang together in the broadest possible sense of the term." [PSIM, 37] This image of the philosopher as a *reflective generalist* recurs frequently in Sellars' metaphilosophical reflections. His most explicit account of the central task confronting contemporary philosophy aligns it firmly with the modernist project of achieving a *rapprochement* between our humanistic understanding of ourselves as free and rational agents, at home among meanings and values, and the thoroughly "disenchanted" picture of the world being painted by an increasingly comprehensive natural science. Sellars thematized this contrast as a confrontation of two "images": the "*manifest image*" whose primary objects are *persons*, beings who can and do conceive of themselves as sentient perceivers, cognitive knowers, and deliberative agents, and the "*scientific image*", whose primary entities are some sophisticated version of "atoms in the void". "The scientific image," Sellars wrote, "presents itself as a *rival* image. From its point of view the manifest image on which it [methodologically] rests is an ‘inadequate’ but pragmatically useful likeness of a reality which first finds its adequate (in principle) likeness in the scientific image." [PSIM, 57] As Sellars saw it, the goal of philosophy was to transform this tension between our lived self-conception and our hard won explanatory understanding of the world into a single "stereoscopic" image, a *synoptic* vision of persons-in-the-world. Much of his philosophical work is addressed to three central moments of this complex undertaking: accommodating the *intentional contents* of thought and language, the *sensuous contents* of perception and imagination, and the

normative dimensions of knowledge and conduct within such a stereoscopic image - all the while resolutely maintaining a robust scientific realism, for "in the dimension of describing and explaining the world, science is the measure of all things, of what is that it is, and of what is not that it is not." [EPM, 173]

Sellars' Philosophy of Science and Epistemology

Sellars' interpretation of the epistemology of natural science departed decisively from the received view according to which explanation was identified with derivation - singular matters of empirical fact being explained by deriving descriptions of them from ("inductively" established) empirical generalizations (along with appropriate statements of initial conditions), and these "empirical laws" in turn being explained by deriving them from theoretical postulates and correspondence rules. On this received Positivist view, theories (e.g., microtheories) explain empirical matters of fact only indirectly, by implying generalizations framed in an observation-language that explain them directly. In consequence, as Hempel pointed out in "The Theoretician's Dilemma", such theories, although perhaps convenient aids to calculation and compact representation, are in principle utterly dispensable.

Sellars regarded this "layer-cake model" or "levels picture" of theories as fundamentally misguided. He argued that there is no autonomous stratum of empirical counterparts to theoretical laws. The empirical generalizations corresponding to theoretical laws become salient only from the theoretical perspective. Generalizations arrived at autonomously at the observational level, however reliable, are not laws of nature, and theories consequently cannot be in the business of explaining such lower-level generalizations by entailing them. Rather, "theories explain laws by explaining why the objects of the domain in question obey the laws that they do to the extent that they do." (LT,123)

> [That is,] they explain why individual objects of various kinds and in various circumstances in the observation framework behave in those ways in which it has been inductively established that they do behave. Roughly, it is because a gas is ... a cloud of molecules which are behaving in certain theoretically defined ways, that it obeys the empirical Boyle-Charles Law. (LT,121)

On Sellars' view stories that postulate "theoretical entities" are not merely manageable second-class surrogates for more complicated and unwieldy stories about entities that we have good, i.e., observational, reasons to believe actually exist. Theoretical entities, rather, are those entities we warrantedly believe to exist for good and sufficient *theoretical* reasons. On this understanding, scientific theories explanatorily "save the appearances" precisely by characterizing the reality of which the appearances are appearances.

Like Quine, Sellars was deeply influenced by the work of Rudolf Carnap. Sellars' sophisticated account of the nature and import of theoretical reasoning in natural science, however, enabled him to develop a systematic naturalistic *alternative* to Quine's influential critique of Carnapian *logical empiricism*. In particular, the epistemological contrast between two sorts of empirical generalizations - those adopted on

narrowly inductive grounds and those expressing constitutive principles of postulational theories adopted on broadly empirical, i.e., explanatory grounds - enabled Sellars to distinguish among three different grades of "observational involvement": observations and general claims individually validated "inductively" by way of *direct* appeals to observational backing, the constitutive posits of postulational theories holistically validated by way of *indirect, explanatory* appeals to observational backing, and purely formal claims expressing necessary conditions for the formulation of scientific hypotheses in general. Consequently, where Quine rejected the classical Kantian analytic-synthetic dichotomy out of hand, Sellars argued that there were two quite different distinctions tangled up in the single dichotomy that Carnap had inherited from the Kantian tradition: the distinction between logical and empirical (matter-of-factual) claims (analytic$_2$-synthetic$_2$), and the distinction between claims whose revision requires abandonment or modification of the system of (theoretical) concepts in terms of which they are framed and claims revisable on the basis of observations formulated in terms of a system of (theoretical) concepts which remained fixed throughout (analytic$_1$-synthetic$_1$). Like Quine, then, Sellars moved decisively away from classical Kantian rationalism, but in the direction of a *Kantian* empiricism which preserved logical space for a theory of semantic meaning and the correlative distinctions between individual matter-of-factual truths and truths which, although belonging to theoretical systems themselves adopted on broadly empirical (synthetic$_2$) grounds, were, relative to such a system, true *ex vi terminorum* (analytic$_1$):

Kant's Rationalism

Grounded in experience ("a posteriori", simple induction)	*Not so grounded* ("a priori")	
Synthetic		**Analytic**
Empirical Laws (regularities)	Arithmetic, Geometry, Mechanics ("synthetic a priori")	Logic
	"Our conceptual framework" (innate principles)	

Kantian Empiricism

Grounded in experience (Empirical)		*Not so grounded*
Synthetic$_2$		**Analytic$_2$ (L-true)**
Synthetic$_1$	**Analytic$_1$**	
Observation, Simple Induction (Operational geometry, mechanics)	Postulation (Physical geometry, idealizing scientific theories, mechanics, micro-physics)	Logic, arithmetic, mathematical analysis (Pure geometry *qua* calculus)

Sellars' Philosophy of Language and Mind

Essential to Sellars' thoroughgoing naturalism is an account of semantic meaning that requires no recourse to irreducibly platonistic or mentalistic idioms. Sellars consequently resolutely locates the normative conceptual order within the causal order and advances a naturalistic interpretation of the modes of causality exercised by linguistic rules centered on the notion of *pattern-governed* behavior, i.e.:

> behavior which exhibits a pattern, not because it is brought about by the intention that it exhibit this pattern, but because the propensity to emit behavior of the pattern has been selectively reinforced, and the propensity to emit behavior which does not conform to this pattern selectively extinguished. (MFC,423)

Pattern-governed behavior characteristic of a species - e.g., the dance of the bees - can arise from processes of natural selection on an evolutionary time scale, but, crucially, pattern-governed behavior can also be developed in individual "trainees" by deliberate selective reinforcement on the part of other individuals, the trainers, acting under the guidance of linguistic *rules of criticism*. In contrast to linguistic *rules of action*, e.g., "Ceteris paribus, one ought to (or: may) say such and such if in circumstances C", which can be efficacious in guiding linguistic activity only to the extent that their subjects already possess the concepts of "saying such-and-such", "being in circumstances C", and, indeed, obeying a rule (i.e., doing something because it is enjoined or permitted by a rule), rules of criticism are ought-to-be's - e.g., "Westminster clock chimes ought to strike on the quarter hour" (LTC,95) - whose subjects, although their performances may be assessed according to such rules, need not themselves have the concept of a rule nor, indeed, any concepts at all. Thus a trainer can be construed as reasoning

> Patterned-behavior of such and such a kind ought to be exhibited by trainees, hence we, the trainers, ought to do this and that, as likely to bring it about that it is exhibited. (MFC,423)

And, in consequence of the conducts of trainers under the guidance of such rules of action, the behavior of a language-learner can come to *conform* to the relevant rules of criticism without his "grasping" them himself in any other sense. "Trainees conform to ought-to-be's because trainers obey corresponding ought-to-do's." (MFC,423)

Against this background, then, Sellars advanced an account of meaning as *functional classification* according to which semantic idioms in the first instance mark contexts within which structurally distinct "natural-linguistic objects" (e.g., utterings or inscribings) are classified in terms of their roles or functions in *language entry transitions* (linguistic responses to perceptual stimuli), *language exit transitions* (causal-linguistic antecedents of non-linguistic conduct), and *intra-linguistic moves* (inferential

transitions from one linguistic representing to another). In particular, ‘means’ is interpreted as a specialized form of the copula, tailored to metalinguistic contexts, according to which the right side of the superficially relational form "___ means …" is properly understood as mentioning or exhibiting a linguistic item.

On Sellars' view, such special copulae and metalinguistic indicators initially arise in response to the need to abstract from our domestic sign designs in order to classify items of different languages on the basis of such functional criteria. In this project, ordinary quotation suffers from a systematic ambiguity regarding the criteria - structural (e.g., geometric, acoustic) or functional - according to which linguistic tokens are classifiable as belonging to this or that linguistic type. Accordingly, Sellars introduced a more straightforward device of two separate styles of quotation marks, star-quotes and dot-quotes, tied respectively to the structural and functional modes of sorting and individuating lexical items. Both star- and dot-quotes are illustrating, and thus indexical, devices, but dot-quotes are, in a sense, doubly so. For, whereas star-quotes form a common noun that is true of inscriptions (empirical structures) appropriately design-isomorphic to the token exhibited between them, dot-quotes form a common noun true of items in any language that play the role or do the job performed in our language by the tokens exhibited between them. In terms of this notational apparatus, then, such semantic claims as, for example,

(1s) (In German) ‘rot’ means red.
(2s) (In German) ‘Schnee ist weiss’ means snow is white.

can be more perspicuously expressed by

(1*) (In the German linguistic community) *rot*s are .red.s.
(2*) (In the German linguistic community) *Schnee ist weiss*s are .snow is white.s.

Once such a distinction between functional and structural classification of linguistic representing items is in hand, it is a straightforward matter to extend it to an account of *mental* representations, i.e., *thoughts*, as well. Unlike Quine, Sellars never abandoned the classical notion of thoughts as intentional *inner episodes* that play a causal-explanatory role vis-à-vis overt, paradigmatically linguistic, behavior. Consistent with his thoroughgoing naturalism, however, correlative to his ontological "linguistic nominalism", Sellars embraced a form of "psychological nominalism", whose leitmotif was

> . . . the denial of the claim, characteristic of the realist tradition, that a "perception" or "awareness" of abstract entities is the root mental ingredient of mental acts and dispositions. (EAE,445)

Instead, Sellars argued, the proper account of the distinctive intentionality of thought is also to be drawn in terms of the forms and functions of natural linguistic items. The positive thesis correlative to psychological nominalism, consequently, is modeled by what Sellars came to call "verbal behaviorism".

> According to VB [verbal behaviorism], thinking ‘that-p,’ where this means ‘having the

> thought occur to one that-p,' has as its primary sense [an event of] saying 'p'; and a secondary sense in which it stands for a short term proximate propensity [dispositional] to say 'p'. (MFC,419)

The origins of Sellars' mature forms of verbal behaviorism lie in the revolutionary theses of his classic essay "Empiricism and the Philosophy of Mind", and, in particular, in his mythical story of our Rylean ancestors and the genius Jones. The story begins *in medias res* with people who have mastered a "Rylean language", a sophisticated expressive system, including logical operators and subjunctive conditionals, whose fundamental descriptive vocabulary pertains to public spatio-temporal objects. Consonant with the Sellarsian account of linguistic meaning as functional classification, this hypothetical Rylean language, although lacking any resources for speaking of inner episodes, thoughts or experiences has been enriched by the fundamental resources of semantical discourse - enabling our ancestors to say of the their peers' utterances that they mean this or that, that they stand in various logical relations to one another, that they are true or false, and so on. In this milieu now appears the genius Jones.

> [In] the attempt to account for the fact that his fellow men behave intelligently not only when their conduct is threaded on a string of overt verbal episodes . . . but also when no detectable verbal output is present, Jones develops a theory according to which overt utterances are but the culmination of a process which begins with certain inner episodes. . . . [His] model for these episodes which initiate the events which culminate in overt verbal behavior is that of overt verbal behavior itself. (EPM,186)

Although the primary use of semantical terms remains the semantical characterization of overt verbal episodes, this Jonesean theory thus carries over the applicability of those semantical categories to its postulated inner episodes. i.e., to (occurrent) thoughts. The point of the Jonesean myth is to suggest that the *epistemological* status of thoughts (qua inner episodes) vis-à-vis candid public verbal performances is most usefully understood as *analogous* to the epistemological status of, e.g., molecules vis-à-vis the public observable behavior of gases.

> [Thought] episodes are 'in' language-using animals as molecular impacts are 'in' gases, not as 'ghosts' are in 'machines'. (EPM,187)

Unlike molecules, however, which are introduced into kinetic gas theory as having a specific empirical character (represented by the posited essentially Newtonian lawfulness of their dynamic interactions), the thought episodes postulated by that theory as covert states of persons are introduced by a *purely functional* analogy. The concept of an occurrent thought is that of a causally-mediating logico-semantic role player, whose determinate empirical/ontological character, and thereby logical space for some form of "identity theory" is so far left open.

> [The] fact that [thoughts] are not introduced as physiological entities does not preclude the possibility that at a later methodological stage they may, so to speak, 'turn out' to be such. Thus, there are many who would say that it is already reasonable to suppose that these

> thoughts are to be ‘identified’ with complex events in the cerebral cortex . . . (EPM,187-8)

Since, on Sellars' account, the concept of a thought is fundamentally the concept of a functional kind, no ontological tensions would be generated by the identification within the scientific image of items belonging to that functional kind with, for instance, states and episodes of an organism's central nervous system. The manifest image's conception of person as thinkers, Sellars concludes, can fuse smoothly with the scientific image's conception of persons as complex material organisms having a determinate physiological and neurological structure.

The idea that the intentionality of the mental is to be understood in terms of epistemologically theoretical transpositions of the semantic categories of public language, themselves interpreted as modes of *functional* classification earn Sellars a definitive place in contemporary analytic philosophy of mind. As Dennett puts it,

> Thus was contemporary functionalism in the philosophy of mind born, and the varieties of functionalism we have subsequently seen are in one way or another enabled, and directly or indirectly inspired, by what was left open in Sellars' initial proposal ... (MTE,341)

Sellars' proposal that we can illuminate the epistemic status of mental concepts by an appeal to the contrast between theoretical and non-theoretical discourse makes sense only against the background of another central element of his philosophical thought, his comprehensive critique of the "myth of the given". The philosophical framework of givenness historically takes on many guises, including not only the idea that empirical knowledge rests on a foundation, but also, crucially, the assumption that the "privacy" of the mental and one's "privileged access" to one's own mental states are fundamental features of experience, both logically and epistemologically prior to all intersubjective concepts pertaining to inner episodes.

Sellars argues, on the contrary, that what begins in the case of inner episodes as a language with a purely theoretical use can acquire a first-person reporting role. It can turn out to be possible to train people, in essence by a process of operant conditioning, to have "privileged access" to some of their inner episodes, that is, to respond directly and non-inferentially to the occurrence of one thought with another (meta-) thought to the effect that one is thinking it. It is a special virtue of this aspect of Sellars' Jonesean story that it shows how the essential intersubjectivity of language can be reconciled with the "privacy" of inner episodes, i.e.,

> . . . that it helps us understand that concepts pertaining to such inner episodes as thoughts are primarily and essentially inter-subjective, as inter-subjective as the concept of a positron, and that the [first-person] reporting role of these concepts . . . constitutes a dimension of [their] use . . . which is built on and presupposes this inter-subjective status. (EPM,189)

At the heart of Sellars' general case against the Myth of the Given is his articulate recognition of the

irreducibly normative character of epistemic discourse.

> The essential point is that in characterizing an episode or a state as that of knowing, we are not giving an empirical description of that episode or state, we are placing it in the logical space of reasons, of justifying and being able to justify what one says. (EPM,169)

Once it is acknowledged that the senses per se grasp no facts, that all knowledge that something is such-and-so (all "subsumption of particulars under universals") presupposes learning, concept formation, and even symbolic representation, it follows that ". . . instead of coming to have a concept of something because we have noticed that sort of thing, to have the ability to notice a sort of thing is already to have the concept of that sort of thing, and cannot account for it." (EPM,176)

Sellars follows Kant in rejecting the Cartesian picture of a sensory-cognitive continuum. The "of-ness" of *sensations* - e.g., a sensation's being of a red triangle or of a sharp shooting pain - he insists, is not the intentional "of-ness" ("aboutness") of thoughts. The "rawness" of "raw feels" is rather their *non-conceptual* character. (cf. IAMBP,376) Consequently, while his *epistemological* views regarding sensory episodes parallel his treatment of the epistemology of occurrent thoughts, Sellars' account of the *ontology* of sensations diverges dramatically from his functionalist account of thoughts.

In a final episode of the Jonesean myth, sensations are introduced as elements of an explanatory account of the occurrence in various circumstances of perceptual cognitions, having determinate semantic contents:

> . . . the hero . . . postulates a class of inner - theoretical - episodes which he calls, say, impressions, and which are the end results of the impingement of physical objects and processes on various parts of the body. . . (EPM,191)

This time, however, the model for Jones' theory is not that of functionally-individuated families of sentences, but rather "a domain of ‘inner replicas’ which, when brought about in standard conditions share the perceptible characteristics of their physical sources". (EPM,191) The leading idea of this model is the occurrence, ‘in’ perceivers of "replicas" *per se*, not of perceivings of "replicas" (which would mistakenly inject into the account of impressions the intentionality of thought), and, although the entities of this *model* are particulars, the entities introduced by the theory are not particulars but rather states of a perceiving subject. Thus, although talk of the "of-ness" of sensations, like that of the "of-ness" of thoughts is, on Sellars' view, fundamentally classificatory, the classification at issue is based not on a functional (logical, semantic) analogy but rather on analogies that, although in the first instance extrinsic and causal, ultimately attribute to sensations a determinate intrinsic content. The specific point of the model is to insist that states of, e.g., sensing [red triangle]ly (to highlight the status of ‘sensation’ as a "verbal noun"), characteristically brought about in normal perceivers in standard conditions by the action of red triangular objects on the eyes, can discharge their explanatory jobs in relation to cognitive perceptual takings (especially non-veridical perceptual judgments) only if they are conceived as resembling and differing from other sensory states - e.g., sensing [green triangular]ly, sensing [red

square]ly, etc. - in a manner formally analogous to the way in which objects of the "replica" model - e.g., red and triangular, green and triangular, and red and square "wafers" - are conceived to resemble and differ from one another.

If that were the end of Sellars' ontological story regarding sensations, matters would be complicated enough. But Sellars proceeds to develop this core account in a variety of different directions, in consequence of which his full theory of sensations has emerged as being one of the most difficult and controversial aspects of his philosophy.

The first complication of Sellars' theory of sensation results from his conviction that, in the case of sensations, Jones' theory is *interpretive*. It does not introduce new domains of entities, but rather reinterprets the categorial/ontological status of sensory contents as states of perceivers. The crux of the original Jonesean theory that the very color quanta of which we are perceptually aware *as* existing in space are instead actually states of persons-qua-perceivers. Already within the manifest image, then, the ontological status ultimately accorded to sensory "content qualia" is incompatible with their being instantiated in physical space.

The second complication of Sellars' theory of sensations arises from the further conclusion that it is this manifest image conception of sensory contents as states of perceivers which must ultimately be synoptically "fused" with the scientific image, and that the latter's commitment to the idea that those perceivers themselves are complex systems of micro-physical particles constitutes a barrier to doing so in any straightforward way. Sellars notoriously concludes that sensory contents can be synoptically integrated into the scientific image only after both they and the currently-fundamental micro-physical particulars of that image as well undergo yet another categorial transposition into a categorially monistic ontology whose fundamental entities are all "absolute processes". Sensings qua absolute processes would then be physical, he writes,

> . . . not only in the weak sense of not being mental (i.e., conceptual), for they lack intentionality, but in the richer sense of playing a genuine causal role in the behavior of sentient organisms. They would, as I have used the terms, be physical-l but not physical-2. Not being epiphenomenal, they would conform to a basic metaphysical intuition: to be is to make a difference. (CL,III,126)

A Final Remark

Lengthy as this discussion has been, it only begins to capture the scope, depth, and systematic character of Sellars' philosophical accomplishments. Many themes from his work have simply gone unmentioned - his anticipation of epistemological externalism and defense of a strong internalist alternative, his insightful analysis of predication and correlative nominalistic alternative to classical Platonistic categorial ontology, his sophisticated account of induction as a form of vindicatory practical reasoning, his significant contributions to ethical theory and the theory of action, and his masterful interpretations of the work of many of the discipline's great historical figures, not as scholarly museum exhibits, but always

as active participants in a continuing philosophical conversation. The bibliographies and Internet resources listed below will point the way to both more comprehensive and more detailed accounts of the work of this towering philosophical figure of the postwar era.

Principal Works by Wilfrid Sellars

Books

- *Pure Pragmatics and Possible Worlds-The Early Essays of Wilfrid Sellars*, [PPPW], ed. by Jeffrey F. Sicha, (Ridgeview Publishing Co; Atascadero, CA; 1980). [Contains a long introductory essay by Sicha and an extensive bibliography of Sellars' work through 1979.]
- *Science, Perception and Reality*, [SPR], (Routledge & Kegan Paul Ltd; London, and The Humanities Press: New York; 1963) [Reissued in 1991 by Ridgeview Publishing Co., Atascadero, CA. This edition contains a complete bibliography of Sellars' published work through 1989.]
- *Philosophical Perspectives*, [PP], (Charles C. Thomas: Springfield, IL; 1967). Reprinted in two volumes, *Philosophical Perspectives: History of Philosophy* and *Philosophical Perspective: Metaphysics and Epistemology*, (Ridgeview Publishing Co.; Atascadero, CA; 1977).
- *Science and Metaphysics: Variations on Kantian Themes*. [S&M], (Routledge & Kegan Paul Ltd; London, and The Humanities Press; New York; 1968). The 1966 John Locke Lectures. [Reissued in 1992 by Ridgeview Publishing Co., Atascadero, CA. This edition contains a complete bibliography of Sellars' published work through 1989, a register of Sellars' philosophical correspondence, and a listing of circulated but unpublished papers and lectures.]
- *Essays in Philosophy and Its History*, [EPH], (D. Reidel Publishing Co.; Dordrecht, Holland; 1975).
- *Naturalism and Ontology*, [N&O], (Ridgeview Publishing Co.; Atascadero, CA: 1979). [An expanded version of the 1974 John Dewey Lectures]
- *The Metaphysics of Epistemology, Lectures by Wilfrid Sellars*, edited by Pedro Amaral, (Ridgeview Publishing Co.; Atascadero, CA; 1989). [Contains a complete bibliography of Sellars' published work through 1989.]
- *Empiricism and the Philosophy of Mind* [EPM*], edited by Robert Brandom, (Harvard University Press.; Cambridge, MA; 1997). [The original, 1956, version of [EPM] (see below), lacking footnotes added in [SPR], with an Introduction by Richard Rorty and Study Guide by Brandom.]

Representational Theories of Consciousness

Consciousness is said in many ways. A theory "of consciousness" can be about practically anything mental; just look through the various current book series and anthologies and journals that feature the word "consciousness" in their titles. But the notions of consciousness addressed here will be only the following: (1) Conscious awareness of one's own mental states, and "conscious states" in the particular sense of: states whose subjects are aware of being in them. (2) "Phenomenal consciousness," as Block (1995) calls it, viz., being in a sensory state that has a distinctive qualitative or phenomenal character. (3) The matter of "what it is like" for the subject to be in a particular mental state, especially for that subject to experience a particular phenomenal property.

The idea of representation has been central in discussions of intentionality for many years, at least since Sellars (1956). But only more recently has it begun playing a major role in theories of consciousness. For each of the three foregoing notions of consciousness, some philosophers have claimed that that type of consciousness is entirely or largely explicable as a kind of representing.

§1: Awareness of One's Own Mental States

Occurrent mental or psychological states fall roughly into three categories: those whose subjects are aware of being in them; those whose subjects are not aware of being in them, but could have been had they taken notice; and those, such as language-processing states, which are entirely subterranean and inaccessible to introspection. A theory is needed to explain these differences.

Two Representational Theories of Awareness

There are two main representational theories of conscious awareness and conscious states. (Important terminological note: Again, I am using the term "conscious state" to mean a mental state that one is aware of being in, and "awareness" as a term for that phenomenon. The phrase "conscious state" has been used in at least one entirely different sense, as by Dretske (1993). Failure to keep these senses straight can lead to much confusion.) The two theories are the Lockean "inner sense" or "higher-order perception" (HOP) theory offered by Armstrong (1968, 1981) (see also Lycan (1987, 1996)), and the "higher-order thought" (HOT) theory defended by Rosenthal (1993) (see also Gennaro (1995) and Carruthers (2000)). According to each of the theories, a subject's awareness of her/his own mental state consists in a representing of that state itself. HOP has it that the representing is done quasi-perceptually, by a set of functionally specified internal attention mechanisms of some kind that scan or monitor first-order mental/brain states. HOT theorists say that merely having a thought about the first-order state will suffice, provided that the thought was directly caused by the state itself.

Each of HOP and HOT easily explains the differences between our three categories of first-order state; a state is, or is not, or could not be a conscious state accordingly as it itself is, or is not, or psychofunctionally could not be the object of a higher-order quasi-perception or thought. Further motivation for a representational theory of awareness is obvious enough as well: In general, to be aware of any thing or state of affairs is to represent that item in some way, and to be unaware or unconscious of it is to fail to represent it. And when we deliberately introspect and thereby become aware of a first-order mental state that we had not realized we were in, the awareness is quasi-perceptual or at least takes the form of a mental state of some kind itself directed upon the first-order state; it feels as though we are "looking at" a particular sector of our cognitive or phenomenal field.

Some Criticisms of Representational Theories of Awareness

Two misguided objections to representational theories need to be warded off. First, it is sometimes complained that such theories do not in any way explain the qualitative or phenomenal character of experience; a mere higher-order representation could hardly bring a phenomenal property into being. So how can they claim to be theories of *consciousness*? But it is no claim of either HOP or HOT (at least as I understand them here) to have explained anything about phenomenal character; they are theories only of the distinction between mental states one is aware of being in and mental states one is not aware of being in. Some other theory must be given of phenomenal character.

Second, some philosophers have feared a regress. If the second-order representation is to confer consciousness on the first-order state, it must itself be a conscious state; so there must be a third-order

representation of it, and so on forever. But HOP and HOT theorists reject the opening conditional premise. The second-order representation need not itself be a conscious state. (Of course, it *may* be a conscious state, if there does happen to be a higher-order representation of it in turn.)

But some further criticisms are not so easily rebutted. (I here ignore objections that apply selectively, to HOP alone or to HOT alone.)

Fallibility. Some philosophers have complained that representational theories leave introspective beliefs too fallible and underrate the privileged access we have to our own mental states. An internal monitor, or whatever device produces a higher-order thought, is a *mechanism*, and every mechanism is fallible and works only contingently. But the objectors contend that our awareness of our own mental states is either infallible or, if not flatly infallible, noncontingently constrained against unreliability. Shoemaker (1994b), for example, grants that pain can "occasionally" escape awareness, but he insists that that could not happen "as a matter of course; it may be true in Lake Wobegon that all of the children are above average, but it can't be true everywhere" (273-274).

There is a special problem about first-order states that have wide intentional content, i.e., content that is not determined by what is in the subject's head but consists in part of relations the subject bears to external objects (Davidson (1987)). Belief contents are normally wide; two people could be molecularly indistinguishable but have different beliefs, if one were on earth and believed something about about water (H_2O), while the other was on Putnam's Twin Earth and had the corresponding belief about the qualitatively similar stuff, XYZ. But (Dretske (1995)) an internal monitor, or whatever device produces a higher-order thought, would be located inside the head and would not be able to look outside the head; so it would not be able to tell, for example, whether its owner's belief was a belief about water or a belief about XYZ. Yet we do know introspectively what it is we believe; so much the worse for the higher-order representation views. (Burge (1988) and Heil (1988) have offered what is now a standard reply to this argument; there has been considerable controversy over that reply.)

Finally, Bar-On and Long (in press) argue more radically that privileged access is not an epistemic matter at all; that is, they say, first-person privilege is not a matter of evidence or especially reliable indication or justification of any other sort. Knowing what one believes or what one phenomenally feels is not in that way like proprioceptively knowing the position of my own limbs without looking. (Bar-On and Long go on to suggest a sophisticated expressive theory of first-person avowals.)

Objections of this sort are really objections to higher-order representation theories considered as theories of self-knowledge and first-person privilege. They do not obviously carry over to the theories' original explanandum, which was the distinction between conscious states and un-, sub-, pre-, or otherwise nonconscious states. It may be that the hypothesis of higher-order representation is needed to explain the latter distinction even if it does not satisfactorily explain privileged access.

False Positives. Shoemaker's complaint was about unfelt pains and other sensations of which, on a representationalist view, one might be systematically unaware. But the fallibility problem for

representational theories gets worse: There is also a danger of false positives. Might not an internal scanner, or whatever mechanism produces a higher-order thought, be defective in that it fires mistakenly, introspecting a visual sensation or a pain that never occurred? A subject might seem to her-/himself to suffer terrible pain for weeks, while actually having no pain at all. (This is not a case of psychosomatic pain; psychosomatic pain is real pain, though of no known physical cause.) Does that consequence of representationalism even make clear sense? Neander (1998) prosecutes this objection; Lycan (1998) rejoins (none too effectively).

Ubiquity. Rey (1983) objects that if all it takes to make a first-order state a conscious state is that the state be the object of a higher-order representation, then consciousness is a lot more prevalent than we think. Any laptop computer, for example, has monitoring devices that keep track of its "psychological" states. Perhaps no existing computer has genuinely psychological states, but Rey argues that once we had done whatever needs to be done in order to fashion a being that did have nonconscious first-order intentional and sensory states, the addition of an internal monitor or two would be a trifling afterthought, hardly the sort of thing that could turn a simply nonconscious being into a conscious being.

This objection clearly calls for a thoughtful response. White (1987) and Lycan (1996) have tried to rebut it.

Computational/Cognitive Overload. Carruthers (2000) points out that, given the richness of a person's conscious experience at a time, the alleged higher-order representing devices would be kept very busy. The higher-order representations would have to keep pace with every nuance of the total experience. The complexity of the experience would have to be matched in every detail by a higher-order perception or thought. It is hard to imagine that a human being would have so great a capacity for complex higher-order representation, much less that a small child or a nonhuman animal would have it. Carruthers concludes that if HOP or HOT is true, then to say the least, few if any creatures besides human adults have conscious experiences. Perhaps representational theorists can live with that apparent consequence; perhaps not.

Thus, representational theories of consciousness in the sense of awareness of one's own mental states have serious difficulties to overcome.

§2: Qualitative/Phenomenal Character

Qualitative features of mental states are often called "qualia" (singular, "quale"). In recent philosophy of mind that term has been used in a number of confusingly different ways, but here I shall use it in the specific, strict sense due to C.I. Lewis (1929): A quale in this sense is an introspectible monadic qualitative or phenomenal property inhering in a mental state, and I shall be talking only of sensory states in particular. A quale can be thought of as the distinctive phenomenal property of an apparent phenomenal individual. (An "apparent phenomenal individual" is anything of the sort that Russell would have taken to be a "sense-datum," such as a colored region of ones visual field, or a heard sound or an experienced smell.) A paradigm of a quale is the color of an after-image. For example, Bertie is

experiencing a green after-image as a result of seeing a red flash bulb go off; the greenness of the after-image is the quale.

Qualia in this sense pose a problem for materialist theories of the mind. For where, ontologically speaking, are they located? Actual Russellian sense-data are immaterial individuals; so the materialist cannot admit that the greenness of the after-image is a property of an actual sense-datum. Nor is it plausible to suggest that the greenness is exemplified by anything physical in the brain (if there is some green physical thing in your brain, you are probably in big trouble). To sharpen the problem, suppose there is no green physical object in Bertie's visible environment either: So there is no green physical thing either inside his head or visibly outside it. But since there is a green thing that he is experiencing, it must after all be a nonphysical, immaterial thing.

There is a representational theory of qualia, due in modern times to Anscombe (1965) and Hintikka (1969); adherents include Kraut (1982), Lewis (1983), Lycan (1987, 1996), Harman (1990), Shoemaker (1994a), Tye (1994, 1995), and Dretske (1995). The representational theory is an attempt to resolve the foregoing dilemma compatibly with materialism. According to it, qualia are actually intentional contents, represented properties of represented objects. Suppose Ludwig is seeing a real tomato in good light, and naturally it looks red to him; there is a corresponding red patch in his visual field. He is visually representing the actual redness of the tomato, and the redness of the "patch" is just the redness of the tomato itself. But suppose George Edward is hallucinating a similar tomato, and there is a tomato-shaped red patch in his visual field just as there is in Ludwig's. George Edward too is representing the redness of an external, physical tomato. It is just that in his case the tomato is not real; it and its redness are intentional inexistents. But the redness is still the redness of the illusory tomato. (Note that the representation going on here is good old first-order representation of environmental features, not higher-order representation as in the HOP and HOT theories of awareness.)

What about Bertie's green after-image? On the representationalist analysis, for Bertie to experience the green after-image is for Bertie to be visually-representing a green blob located at such-and-such a spot in the room. Since in reality there is no green blob in the room with Bertie, his visual experience is unveridical; after-images are illusions. The quale, the greenness of the blob, is (like the blob itself) an intentional inexistent.

And that is how the representationalist resolves our dilemma. There is a green thing that Bertie is experiencing, but it is not an actual thing. That "there is" is the same lenient non-actualist "there is" that occurs in "There is something that Bertie believes in but that doesn't exist" and in "There is a mythical god that the Greeks worshipped but no one worships any more." (In defending his sense-data, Russell mistook a nonactual material thing for an actual immaterial thing.)

Most representationalists agree that the representation of color and other sensible properties is "nonconceptual" in some sense--at least in that the qualitative representations need not be easily translatable into the subject's natural language. Of course, some psychosemantics would be needed to explain what it is in virtue of which a brain item represents greenness in particular. Dretske (1995) offers one, as does Tye (1995); both accounts are teleologized versions of "indicator" semantics.

On pain of circularity, the representational theory requires color realism. In this discussion, "green" has meant the objective, public property that inheres in some physical objects. (One could not, without circularity, explicate phenomenal greenness in terms of represented real-world color and then turn around and construe real physical greenness as a disposition to produce sensations of phenomenal greenness.) What sort of real-world property is an "objective," physical color? There is a variety of realist answers, though none of them is uncontroversial. (Dretske (1995), Tye (1995), Lycan (1996) and Lewis (1997) each gesture toward one.)

Of course, the mere representation of redness does not suffice for phenomenal red, for something's looking red to a subject. (One could say the word "red" aloud, or semaphore it from a cliff, or send it in Morse code, or write the French word "rouge" on a blackboard, or point to a color chip.) The representation must be specifically a visual representation, produced by either a normal human visual system or by something functionally like one. Thus, the representational theory of qualia cannot be purely representational, but must appeal to some further factor. Dretske (1995) cites only the fact that visual representation is sensory and what he calls "systemic." Tye (1995) requires that the representation be nonconceptual and "poised," and also argues that visual representations of color would differ from other sorts of representations in being accompanied by further representational differences. Lycan (1996) appeals to functional considerations. (The latter mixed view is what Block (1996) calls "quasi-representationism.")

Thus we may distinguish different grades of representationalism about qualia. *Purest* representationalism would be the view that representation is all it takes to make a quale; but no one holds that view. *Strong* representationalism is what is defended by Dretske, Tye and Lycan: that representation of a certain kind suffices for a quale, where the kind can be specified in functionalist or other familiar materialist terms, without recourse to properties of any ontologically new sort. *Weak* representationalism says only that qualitative states have representational content, which admission is compatible with qualia also necessarily involving features that are ontologically "new" (Block (1990, 1996), Chalmers (1996)). (There is a further question, of whether qualia themselves, in our very specific sense, exhaust all of what has usually been thought of as a sensory state's overall phenomenal character. Lycan (1998) argues that they do not.) Throughout the rest of this article, unless otherwise noted, "representationalism" shall mean the strong representationalist view.

§2.1: Arguments in Favor of the Representational Theory of Qualia

There are at least four direct arguments in favor of the representational theory.

First, the theory is the only very promising way to preserve materialism while accommodating qualia. For the only viable alternative resolution of our Bertie dilemma seems to be belief in actual Russellian sense-data or at least in immaterial properties. (The anti-materialist may not mind sense-data ontologically, but s/he will also inherit the nasty epistemological problems that Russell never succeeded in overcoming; the external world is a nice thing to have. More likely, an opponent will hold the line at

property dualism, as do Jackson (1982) and Chalmers (1996).) A materialist might suggest a type-identity of Bertie's phenomenal greenness with something neurophysiological, but that would be to do away with the important claim that greenness itself, rather than some surrogate property, figures in Bertie's experience; the suggestion would be an error theory, and would have to explain away the intuition that, whatever the ultimate ontology, Bertie really is experiencing an instance of greenness.

Second (Dretske (1996)), there is nothing intrinsic to the brain that constitutes the difference between a red quale and a green one; unless there are Russellian sense-data or at least immaterial properties, what distinguishes the two qualia must be relational, and the only obvious candidate is, *representing* red or green. (A surprising but harmless consequence of this view is that qualia in our strict (C.I.-)Lewisian sense are not themselves properties of the experiences that present them: Qualia are represented properties of represented objects, and so they are only intentionally present in experiences. As before, the relevant properties *of* the experiences are, representing this quality or that. Of course, one could neologize slightly and speak of "qualia" as properties of experiences, identifying them with representational features.) But to this second argument the neurophysiological type-identity theorist would have a stronger rebuttal.

Third, we distinguish between veridical and unveridical visual experiences. How so? I would take it to be fairly uncontentious that Bertie's experience is as of a green blob and has greenness as an intentional object, and that what the experience reports is false. (The only type of theorist I know who disputes this is an unreconstructed Russellian sense-datum merchant: If one thinks of the after-image itself as an actually and independently existing individual--indeed one of the world's basic building blocks--one will not also think of it as representational.) Moreover, the experience's veridicality condition, i.e., there being a green blob where there seems to Bertie to be one, seems to exhaust not only its representational content but its qualitative content. Once the *greenness* has already been accounted for, what qualitative content is left? (But we shall see in §3 below that that question has a serious nonrhetorical answer.)

Fourth, the transparency argument (Harman (1990)): We normally "see right through" perceptual states to external objects and do not even notice that we are *in* perceptual states; the properties we are aware of in perception are attributed to the objects perceived. "Look at a tree and try to turn your attention to intrinsic features of your visual experience. I predict you will find that the only features there to turn your attention to will be features of the presented tree, including relational features of the tree ‘from here’" (p. 39). Tye (1995) extends this argument to bodily sensations such as pain.

The transparency argument can be extended also to the purely hallucinatory case. Suppose you are looking at a real, richly red tomato in good light. Suppose also that you then hallucinate a second, identical tomato to the right of the real one. (You may be aware that the second tomato is not real.) Phenomenally, the relevant two sectors of your visual field are just the same; the appearances are just the same in structure. The redness involved in the second-tomato appearance is exactly the same property as is involved in the first. But if we agree that the redness perceived in the real tomato is just the redness of the tomato itself, then the redness perceived in the hallucinated tomato--the red quale involved in the second-tomato appearance--is just the redness of the hallucinated tomato itself.

§2.2: Objections to the Representational Theory of Qualia

Objections to the representational theory come mainly in the form of counterexamples: cases in which either two experiences share their intentional content and differ in their qualia or they differ entirely in their intentional content but share qualia. Peacocke (1983) gave three examples of the former kind, Block (1990) one of the latter. (Block (1995, 1996) also offers some of the former kind; for discussion, see Lycan (1996).)

In Peacocke's first example, your experience represents two (actual) trees, at different distances from you but as being of the same physical height and other dimensions; "[y]et there is also some sense in which the nearest tree occupies more of your visual field than the more distant tree" (p. 12). That sense is a qualitative sense, and Peacocke maintains that the qualitative difference is unmatched by any representational difference. The second and third examples concern, respectively, binocular vision and the reversible-cube illusion. In each case, Tye (1995) and Lycan (1996) have rejoined that there are after all identifiable representational differences constituting the qualitative differences.

Block appeals to an "Inverted Earth," a planet exactly like Earth except that its real physical colors are (somehow) inverted with respect to ours. The Inverted Earthlings' speech sounds just like English, but their intentional contents in regard to color are inverted relative to ours: When they say "red," they mean green (if it is green Inverted objects that correspond to red Earthly objects under the inversion in question), and green things *look* green to them even though they call those things "red." Now, an Earthling victim is chosen by the customary mad scientists, knocked out, fitted with color inverting lenses, transported to Inverted Earth, and repainted to match that planet's human skin and hair coloring. Block contends that after some length of time--a few days or a few millennia--the victim's word meanings and propositional-attitude contents and all other intentional contents will shift to match the Inverted Earthlings' contents, but, intuitively, the victim's qualia will remain the same. Thus, qualia are not intentional contents.

The obvious representationalist reply is to insist that if the intentional contents would change, so too would the qualitative contents; what is Block's argument for denying this? Block's nearly explicit argument is that qualia are "narrow," in that they supervene on head contents (on this view, two molecularly indistinguishable people could not experience different qualia), while the intentional contents shift under environmental pressure precisely because they are "wide." If qualia are indeed narrow, and all the intentional contents are wide and would shift, then Block's argument succeeds. (Stalnaker (1996) gives a version of Block's argument that does not depend on the assumption that qualia are narrow; Lycan (1996) rebuts it.)

Three replies are available, then: (i) To insist that not all the intentional contents would shift. Word meanings would shift, but it does not follow that visual contents ever would. (ii) To hold that although all the ordinary intentional contents would shift, there is a special class of narrow though still representational contents underlying the wide contents; qualia can be identified with the special narrow contents. (iii) To deny that qualitative content is narrow and argue that it is wide, i.e., that two molecularly indistinguishable people could indeed experience different qualia. This last is the position

that Dretske (1996) has labelled "phenomenal externalism."

Reply (i) has not been much pursued. (ii) has, a bit, by Tye (1994) and especially Rey (1998). Rey argues vigorously that qualia are narrow, and then offers a narrow representational theory. (But it turns out that Rey's theory is not a theory of qualia in the strict Lewisian sense of quale used here; see below.)

Reply (iii), phenomenal externalism, has been defended by Dretske (1995, 1996), Tye (1995) and Lycan (1996). A number of people (even Tye himself (1998)) have since called the original contrary assumption that qualia are narrow a "deep / powerful / compelling" intuition, but it proves to be highly disputable. Here are two arguments, though not very strong arguments, for the claim that qualia are wide.

First, if the representational theory is correct, then qualia are determined by whatever determines a psychological state's intentional content; in particular, the color properties represented are taken to be physical properties instanced in the subject's environment. What determines a psychological state's intentional content is given by a *psychosemantics*, in Fodor's (1987) sense. But every known plausible psychosemantics makes intentional contents wide. Of course, the representational theory is just what is in question; but:

Second, suppose qualia are narrow. Then Block's Inverted Earth argument is plausible, and it would show that either qualia are narrow functional properties or they are properties of a very weird kind whose existence is suggested by nothing else we know (see Ch. 6 of Lycan (1996)). But qualia are not functional properties, at least not narrow ones: Recall the Bertie dilemma. Also, qualia are monadic properties, while functional properties are all relational; and see further Block's anti-functionalist arguments in Block (1978). So, either qualia are wide or weirdness is multiplied beyond necessity. Of course, that dichotomy will be resisted by anyone who offers a narrow representationalist theory as in (ii) above.

§2.4: Arguments For Narrow Qualia

Although until a few years ago the assumption that qualia are narrow had been tacit and entirely undefended, opponents of representationalism have since begun defending it with vigor. Here are (only) some of their arguments, with sample replies.

Introspection. An Earthling suddenly transported to Inverted Earth or some other relevant sort of Twin Earth would notice nothing introspectively, despite a change in representational content; so the quale must remain unchanged and so is narrow.

Reply: The same goes for propositional attitudes, i.e., the transported Earthling would notice nothing introspectively. Yet the attitude contents are still wide. Wideness does not entail introspective change under transportation.

Narrow content. In the propositional-attitude literature, the corresponding transportation argument has

been taken as the basis of an argument for "narrow content," viz., for something that is intentional content within the meaning of the act but is narrow rather than, as usual, wide. The self-knowledge problem aforementioned, and the problem of "wide causation" (Fodor (1987), Kim (1995)), have also been used to motivate narrow content. And, come to think of it, any general argument for narrow content will presumably apply to sensory representation as well as to propositional attitudes. If there is narrow content at all, and sensory content is representational, then probably sensory states have narrow content too. Thus, qualia can and should be taken to be the narrow contents of such states.

Replies: First, this begs the question against the claim that qualia are wide. Even if there are indeed narrow contents impacted within sensory states, independent argument is needed for the identification of qualia with those contents rather than with wide contents. Second and more strongly, narrow sensory contents still would not correspond to qualia in the Lewisian sense. The redness of a patch in my visual field is (so far as has been shown) still a wide property, even if some other, narrow property underlies it in the same way that mysterious, ineffable narrow contents are supposed to underlie beliefs and desires.

Modes of Presentation. (Rey (1998)) There is no such thing as representation without a mode of presentation. If a quale is a representatum, then it is represented under a mode of presentation, and modes of presentation may be narrow even when the representational content itself is wide. Indeed, many philosophers of mind take modes of presentation to be internal causal or functional roles played by the representations in question. Surely they are strong candidates for qualitative content. Are they not narrow qualia?

Reply: Remember, the qualia themselves are properties like phenomenal greenness and redness, which according to the representational theory are representata. The modes or guises *under which* greenness and redness are represented in vision are something else again.

It can plausibly be argued that such modes and guises are qualitative or phenomenal properties of some sort, perhaps higher-order properties. See the next section.

Qualitative but Nonrepresenting States. (Rey (1998)) Even if perceptual states are representational, bodily sensations and moods do not have that same feature. Yet bodily sensations and moods do have qualitative character. "Many have noted that states like that of elation, depression, anxiety, pleasure, orgasm seem to be just overall states of *oneself*, and not features of presented objects" (p. 441, italics original).

Here the representational theorist must tough it out, and insist both that bodily sensations and moods do have intentional content and that their intentional content exhausts their qualitative character. Of course, each of those claims, especially the first, requires hefty independent defense. It is easy enough to argue that pains and tickles and even orgasms have some representational features (see Tye (1995) and Lycan (1996)). For example, a pain is felt as being in a certain part of one's body, *as if* that part is disordered in a certain way; that is why pains are described as "burning," "stabbing," "throbbing" and the like. It is harder to show that the sensations' qualitative contents are exhausted by their representational features. It is perhaps still harder to maintain that a mood has intentional content, though it could be argued that a

state of elation, for example, represents *the world* as a beautiful and exciting place.

Memory. (Block (1996)) "[Y]ou remember the color of the sky on your birthday last year, the year before that, ten years before that, and so on, and your long-term memory gives you good reason to think that the phenomenal character of the experience has not changed.... Of course, memory *can* go wrong, but why should we suppose that it **must** go wrong here?" (pp. 43-44, italics and boldface original). The idea is that memory acts as a check on the qualia, and can be used to support the claim that the qualia have remained unchanged despite the wholesale shift in representational contents.

Reply: Memory contents are wide, and so by Block's own reasoning they will themselves undergo the representational shift to the Inverted-Earth complementary color. Thus, your post-shift memories of good old Earth are false. When you say or think to yourself, "Yes, the sky looks as blue as it did thirty years ago," you are not expressing the same memory content as you would have when you had just arrived on Inverted Earth. You are now remembering or remembering that the sky looked yellow, since for you "blue" now means yellow. And that memory is false, since on the long-ago occasion the sky looked blue to you, not yellow; memory is not after all a reliable check on the qualia. (Lycan (1996) takes this line; Tye (1998) expands it in more detail.)

Hardly anyone will accept all of the foregoing replies. But no one should now find it obvious either that qualia are narrow or that they are wide. The matter is likely to remain controversial for some time to come.

§3: What It's Like

Some philosophers (e.g., Dretske (1995), Tye (1995)) use this troublesome expression simply to mean a quale, and this is one of the two meanings it has had in recent philosophy of mind. But in the opening paragraph of this article, the phrase was introduced in the context, "‘what it is like’ for the subject to be in a particular mental state, especially for that subject to experience a particular phenomenal property [or quale]," which suggests that there is another sense in which (when the mental state does involve a quale) the "what it's like" is something over and above the quale itself. In fact, since this second "what it's like" is itself a property of the quale, it cannot very well be identical with the quale. (Block (1995), like many other writers, fails to distinguish this from "phenomenal consciousness" in our original sense. But Carruthers (2000) elaborates nicely on the distinction.)

Here are two further reasons for maintaining such a distinct sense of the phrase. First, Armstrong (1968), Nelkin (1989), Rosenthal (1991), and Lycan (1996) have argued that qualia can fail to be conscious in the earlier sense of awareness; a quale can occur without its being noticed by its subject. But in such a case, there is a good sense in which it would not be like anything for the subject to experience that quale. (Of course, in the first, Dretske-Tye sense there would be something it was like, since the quale itself is that. But in another sense, if the subject is *entirely unaware* of the quale, it is odd even to speak of the subject as "experiencing" it, much less of there being something it is like for the subject to experience it.) So even in the case in which one is aware of one's quale, the second type of "what it's like" requires

awareness and so is something distinct from the quale itself.

Second, a quale can be described in one's public natural language, while what it is like to experience the quale seems to be ineffable. Suppose Ludwig asks Bertie, "How, exactly, does the after-image look to you as regards color?" Bertie replies, "I told you, it looks green." "Yes," says Ludwig, "but can you tell me what it's like to experience that ‘green’ look?" "Well, the image looks the same color as that," says Bertie, pointing to George Edward's cloth coat. "No, I mean, can you tell me what it's like intrinsically, not comparatively?" "Um,...." --In one way, Bertie can describe the phenomenal color, paradigmatically as "green." But when asked what it is like to experience that green, he goes mute. So there is a difference between (a) "what it's like" in the bare sense of the quale, the phenomenal color that can be described using ordinary color words, and (b) "what it's like" to experience that phenomenal color, which cannot easily be described in public natural language at all.

It is the second sense of "what it's like" that figures in anti-materialist arguments from subjects' "knowing what it's like," primarily Nagel's (1974) "Bat" argument and Jackson's (1982) "Knowledge" argument. Jackson's character Mary, a brilliant color scientist trapped in an entirely black-and-white laboratory, nonetheless becomes omniscient as regards the physics and chemistry of color, the neurophysiology of color vision, and every other public, objective fact conceivably relevant to human color experience. Yet when she is finally released from her captivity and ventures into the outside world, she sees colors for the first time, and learns something: namely, she learns what it is like to see red and the other colors. Thus she seems to have learned a new fact, one that by hypothesis is not a public, objective fact. It is an intrinsically perspectival fact. This is what threatens materialism, since according to that doctrine, every fact about every human mind is ultimately a public, objective fact.

Upon her release, Mary has done two things: She has at last hosted a red quale, and she has learned what it is like to experience a red quale. In experiencing it she has experienced a "what it's like" in the first of our two senses. But the fact she has learned has the ineffability characteristic of our second sense of "what it's like"; were Mary to try to pass on her new knowledge to a still color-deprived colleague, she would not be able to express it in English.

We have already surveyed the representational theory of qualia. But there are also representational theories of "what it's like" in the second sense. A common reply to the arguments of Nagel and Jackson (Horgan (1984), Van Gulick (1985), Churchland (1985), Tye (1986), Lycan (1987, 1990, 1996), Loar (1990), Rey (1991), Leeds (1993)) is to note that a knowledge difference does not entail a difference in fact known, for one can know a fact under one representation or mode of presentation but fail to know one and the same fact under a different mode of presentation. Someone might know that water is splashing but not know that H_2O molecules are moving, and vice versa; someone might know that person X is underpaid without knowing that she herself is underpaid, even if she herself is in fact person X. Thus, from Mary's before-and-after knowledge difference, Jackson is not entitled to infer the existence of a new, weird fact, but at most that of a new way of representing. Mary has not learned a new fact, but has only acquired a new, introspective or first-person way of representing one that she already knew in its neurophysiological guise.

(As noted above, the posited introspective modes of presentation for qualia in the Lewisian sense are strong candidates for the title of qualia in a distinct, higher-order sense of the term, and they may well be narrow rather than wide. This is what Rey (1998) seems to be talking about.)

This attractive response to Nagel and Jackson--call it the "perspectivalist" response--requires that the first-order qualitative state itself be represented (else how could it be newly known under Mary's new mode of presentation?). And that hypothesis in turn encourages a representational theory of higher-order conscious awareness and introspection. Since we have seen that representational theories of awareness face powerful objections, the perspectivalist must either buy into such a theory despite its liabilities, or find some other way of explicating the idea of an introspective or first-person perspective without appealing to higher-order representation. The latter option does not seem promising.

The Unity of Consciousness

Our consciousness evidences a striking unity. As we will see, unified consciousness can take more than one form but the following form is central. When we are conscious, we are conscious of the contents of a number of conscious states at the same time and as related to one another in various ways. I am aware not of A and, separately, of B and, separately, of C, but of A-and-B-and-C, all at the same time -- or better, as all parts of the contents of a single conscious state. Since at least the time of Kant (1781/7), this phenomenon has been called the *unity of consciousness*.

Historically, the notion of the unity of consciousness has played a very large role in thought about the mind. Indeed, as we will see, it figured centrally in some of the most influential arguments about the mind from the time of Descartes to the 20th century. In the early part of the 20th century, the notion largely disappeared for a time. Analytic philosophers began to pay attention to it again only in the 1960s. We will trace this history up to about 1900. At that point, we will have to delineate the unity of consciousness more carefully and examine some evidence from neuropsychology because both are necessary to understand the recent work on the issue. We will then examine that work. We will conclude with the question of whether consciousness' being unified has implications for other issues concerning consciousness and the mind.

1. History of the Notion

The unity of consciousness has had an interesting history in philosophy and psychology. Taking Descartes to be the first major philosopher of the modern period, the unity of consciousness was central to the study

of the mind for the whole of the modern period until the 20th century. The notion figured centrally in the work of Descartes, Leibniz, Hume, Reid, Kant, Brentano, James -- indeed, in most of the major precursors of contemporary philosophy of mind and cognitive psychology. It played a particularly important role in Kant's work (Brook, 1994).

A couple of examples will illustrate the role that the notion of the unity of consciousness played in this long literature. Consider a classical argument for dualism (the view that the mind is not the body, indeed is not made out of matter at all). It starts like this:

> When I consider the mind, that is say, myself inasmuch as I am only a thinking thing, I cannot distinguish in myself any parts, but apprehend myself to be clearly one and entire. [Descartes, 1641, p. 196]

Descartes then asserts that if the mind is not made up of parts, it cannot be made of matter, presumably because, as he saw it, anything material has parts. He then goes on to say that this would be enough to prove dualism by itself, had he not already proved it elsewhere. Notice where it is that I cannot distinguish any parts. It is in the unified consciousness that I have of myself.

Here is another, somewhat more elaborate argument based on unified consciousness. The conclusion will be that unified consciousness could never be achieved by any system of components acting in concert. William James' well-known version of the argument starts as follows:

> Take a sentence of a dozen words, take twelve men, and to each one word. Then stand the men in a row or jam them in a bunch, and let each think of his word as intently as he will; nowhere will there be a consciousness of the whole sentence. [James, 1890, Vol. 1, p.160]

James generalizes this observation to all conscious states. To get dualism out of this, we need to add a premise: that if the mind were made out of matter, conscious states would have to be distributed over some group of components in some relevant way. But, this thought experiment is meant to show, conscious states cannot be so distributed. Therefore, the conscious mind is not made out of matter. Q.E.D. Call the argument that James is using here the Unity Argument. Clearly, the idea that our consciousness of, in this case, the parts of a sentence is unified is at the center of the Unity Argument. Like the first, this argument goes all the way back to Descartes. Versions of it can be found in thinkers otherwise as different from one another as Leibniz, Reid, and James. The Unity Argument continued to be influential into the 20th century. That the argument was considered to be a powerful reason for concluding that the mind is not the body is illustrated in a somewhat backhanded way by Kant's treatment of it (as he found it in Descartes and Leibniz, not James, of course).

Kant did not think that we could *demonstrate* anything about the nature of the mind, including whether or not it is made out of matter. To make the case for this view, he had to show that all existing arguments that the mind is not material do not work and he set out to do just this in the chapter in the *Critique of Pure Reason* on the Paralogisms of Pure Reason (1781) (paralogisms are faulty inferences about the nature of the mind). The Unity Argument is the target of a major part of that chapter; if one is going to

show that we cannot know what the mind is like, we must dispose of the Unity Argument, which purports to show that the mind is not made out of matter. Kant's argument that the Unity Argument does not support dualism is simple. He urges that the idea of unified consciousness being achieved by something that has no parts or components is no less mysterious than its being achieved by a system of components acting together (1781, A352). Remarkably enough, even though no philosopher has ever met this challenge of Kant's and no account exists of what an immaterial mind *not* made out of parts might be like, philosophers continued to rely on the Unity Argument until well into the 20th century. It may be a bit difficult for us to capture this now but the idea that unified consciousness could not be realized by any system of components, and *a fortiori* any system of material components, had a strong intuitive appeal for a long time.

The notion that consciousness is unified was also central to one of Kant's own famous arguments, his ‘transcendental deduction of the categories’. In this argument, boiled down to its essentials, Kant claims that in order to tie various objects of experience together into a single unified conscious representation of the world, something that he simply assumed that we could do, we must be able to apply certain concepts to the items in question. In particular we have to apply concepts from each of four fundamental categories of concept: quantitative, qualitative, relational, and what he called ‘modal’ concepts. Modal concepts concern whether an item might exist, does exist, or must exist. Thus, the four kinds of concept are concepts for how many units, what features, what relations to other objects, and what existence status are represented in an experience.

It was relational concepts that most interested Kant and of relational concepts, he thought the concept of cause-and-effect to be by far the most important. Kant wanted to show that natural science (which for him meant primarily physics) was genuine knowledge (he thought that Hume's skeptical treatment of cause and effect relations challenged this status). He believed that if he could prove that we must tie items in our experience together causally if we are to have a unified awareness of them, he would have put physics back on "the secure path of a science". The details of his argument have exercised philosophers for over two hundred years. We will not go into them here, but the argument illustrates how central the notion of the unity of consciousness was in Kant's thinking about the mind and its relation to the world.

Even though the unity of consciousness had been at the center of pre-20th century research on the mind, early in the 20th century the notion almost disappeared. Logical atomism in philosophy and behaviorism in psychology were both unsympathetic to the notion. Logical atomism focused on the atomic elements of cognition (sense data, simple propositional judgments, etc.), rather than on how these elements are tied together to form a mind. Behaviorism urged that we focus on behavior, the mind being either a myth or at least something that we cannot and do not need to study in a science of the human person. This attitude extended to consciousness, of course. The philosopher Daniel Dennett summarizes the attitude prevalent at the time this way:

> Consciousness appear[ed] to be the last bastion of occult properties, epiphenomena, immeasurable subjective states -- in short, the one area of mind best left to the philosophers. Let them make fools of themselves trying to corral the quicksilver of ‘phenomenology’ into a respectable theory. [1978, p. 149]

The unity of consciousness next became an object of serious attention in analytic philosophy only as late as the 1960s. In the years since, new work has appeared regularly. The accumulated literature is still not massive but the unity of consciousness has once again become an object of serious study. Before we examine the more recent work, we need to explicate the notion in more detail than we have done so far and introduce some empirical findings. Both are required to understand recent work on the issue.

2. What the Unity of Consciousness Is

To expand on our earlier notion of the unity of consciousness, we need to introduce a pair of distinctions. Current work on consciousness labors under a huge, confusing terminology. Different theorists talk about access consciousness, phenomenal consciousness, self-consciousness, simple consciousness, creature consciousness, state consciousness, monitoring consciousness, awareness as equated with consciousness, awareness distinguished from consciousness, higher order thought, higher order experience, qualia, the felt qualities of representations, consciousness as displaced perception, ... and on and on and on. We can ignore most of this profusion but we do need two distinctions: between consciousness of objects and consciousness of our representations of objects, and between consciousness of representations and consciousness of self.

Consciousness of objects is closely related to sentience and to being awake. It is (at least) being in a certain informationally and behaviorally responsive state to one's immediate environment. It is the ability, for example, to process and act responsively to information about food, friends, foes, and other items of relevance. One finds consciousness of objects in creatures much less complex than human beings. It is what we (at any rate first and primarily) have in mind when we say of some person or animal as it is coming out of a general anaesthesia, ‘It is regaining consciousness’. Consciousness of objects is not just any form of informational access to the world. It is *knowing about, being conscious of,* things in the world. We will return to this point in a moment.

We are conscious of our representations when we are conscious, not (just) of some object, but of our representations: ‘I am seeing [as opposed to touching, smelling, tasting] and seeing clearly [as opposed to dimly].’ Consciousness of our own representations it is the ability to process and act responsively to information about oneself, but it is not just any form of such informational access. It is *knowing about, being conscious of,* one's own psychological states. In Nagel's famous phrase (1974), when we are conscious of our representations, it is ‘like something’ to have them. If, as seems likely, there are forms of consciousness that do not involve consciousness of objects, they might well consist in consciousness of representations, though some theorists would insist that this kind of consciousness is not *of* representations either (*via* representations, perhaps, but not *of* them).

The distinction just drawn between consciousness of objects and consciousness of our representations of objects may seem to be similar to Block's (1995) well-known distinction between P- [phenomenal] and A- [access] consciousness. Here is his definition of ‘A-consciousness’: "A state is A-conscious if it is poised for direct control of thought and action" (1995, p. 233). He tells us that he cannot define ‘P-

consciousness' in any "remotely noncircular way" but will use it to refer to what he calls "experiential properties", what it is like to have certain states (1995, p. 231). Our consciousness of objects may appear to be rather like Block's A-consciousness. It is not. It is a form of P-consciousness. Consciousness of an object is -- how else can we put it? -- *consciousness* of the object. Even if consciousness *just is* informational access of a certain kind (something that Block would deny), it is not all forms of informational access and we are talking about *conscious* access here. Recall the idea that it is like something to have a conscious state. Other closely related ideas are that in a conscious state, something appears to one, that conscious states have a 'felt quality' (see the entry on qualia). A term for all this is *phenomenology:* conscious states have a phenomenology. (Thus some philosophers speak of *phenomenal consciousness* here.) We could now state the point we are trying to make this way. If I am conscious of an object, then it is like something to have that object as the content of a representation.

(Some theorists would insist that this last statement be qualified. While such a representation of an object may provide everything that a *representation* has to have for its contents to be like something to me, they would urge, something more is needed. Different theorists would add different elements. For some, I would have to be aware, not just of the object, but of my representation of it. For others, I would have to direct attention a certain way or something. We cannot go into this controversy here. Here we are merely making the point that consciousness of objects is more than Block's A-consciousness.)

Consciousness of self involves, not just consciousness of states that it is like something to have, but consciousness of the thing that has them, i.e., of oneself. It is the ability to process and act responsively to information about oneself, but again it is more than that. It is *knowing about, being conscious of,* oneself, indeed *of* oneself *as* oneself. Consciousness of oneself in this way is often called consciousness of oneself as *the subject of experience.* Consciousness of oneself as oneself seems to require an indexical ability and a rather special indexical ability at that, not just an ability to pick out something out but to pick something out *as oneself.* Human beings have such self-referential indexical ability. Whether any other creatures have it is controversial. The leading nonhuman candidate would be chimpanzees and other primates who have been taught enough language to use first-person pronouns.

The literature on consciousness sometimes fails to distinguish consciousness of objects, consciousness of one's own representations, and consciousness of self, or treats one of the three, usually consciousness of one's own representations, as the totality of consciousness. (There may also be conscious states that do not have objects, yet are not consciousness of a representation either. We cannot pursue that complication here.) The term 'conscious' and cognates are ambiguous in everyday English. We speak of someone regaining consciousness -- where we mean simple consciousness of the world. Yet we also say things like, 'She wasn't conscious of what motivated her to say that' -- where we do not mean that she lacked either consciousness of the world or consciousness of self but rather that she was not conscious of certain things *about herself,* specifically, certain of her own representational states. To understand the unity of consciousness, it is important to make these distinctions. The reason is this: the unity of consciousness takes a somewhat different form in consciousness of self than it takes in either consciousness of one's own representations or consciousness of objects.

So what is unified consciousness? As we said, the predominant form of the unity of consciousness is

being aware of a number of things at the same time. Intuitively, this is the notion of a number of representations being aspects of a single encompassing conscious state. A more informative idea can be gleaned from the way philosophers have written about unified consciousness. As emerges from what they have said, the central feature of unified consciousness is taken to be something like this:

> Unity of consciousness: A group of representations being related to one another such that to be conscious of any of them is to be conscious of others of them and of the group of them as a single group.

Call this notion UC(1). Now, unified consciousness *of some sort* can be found in all three of the kinds of consciousness we delineated. (It can be found in a fourth, too, as we will see in a moment.) We can have unified consciousness of: objects represented to us; the representations themselves; and oneself, the thing having the representations. In the first case, the represented objects would appear as aspects of a single encompassing conscious states. In the second case, the representations themselves would thus appear. In the third case, one is aware of oneself as a single, unified subject. Does UC(1) fit all three (or all four, including the fourth yet to be introduced)? It does not. At most, it fits the first two. Let us see how this unfolds.

2.1 Unity of consciousness of objects

Unified consciousness of objects is the consciousness that one has of the world around one (including one's own body) as aspects of a single world, of the various items in it as linked to other items in it. What makes it *unified* can be illustrated by an example. Suppose that I am aware of the computer screen in front of me and also of the car sitting in my driveway. If awareness of these two items is not unified, I will lack the ability to compare the two. If I cannot bring the car as I am aware of it to the state in which I am aware of the computer screen, I could not answer questions such as, Is the car the same color as the WordPerfect icon?, or even, As I am experiencing them, is the car to the left or to the right of the computer screen? We can compare represented items in these ways only if we are aware of both items together, as parts of the same field or state or act of conscious. That is what unified consciousness does for us. UC(1) fits this kind of unified consciousness well. There are a couple of disorders of consciousness in which this unity seems to break down or be missing. We will examine them shortly.

2.2 Unified consciousness of one's own representations

Unified consciousness of one's own representations is the consciousness that we have of our representations, consciousness of our own psychological states. The representations by which we are conscious of the world are particularly important but, if those theorists who maintain that there are forms of consciousness that do not have objects are right, they are not the only ones. What makes consciousness of our representations unified? We are aware of a number of representations together, in such a way that they appear as aspects of a single state of consciousness. As with unified consciousness of the world, here too we can compare items of which we have unified consciousness. For example, we can compare what it is like to *see* an object to what it is like to *touch* the same object. Thus, UC(1) fits this kind of unified

consciousness well, too.

2.3 Unified consciousness of self

When one has unified consciousness of self, one is aware of oneself not just as the subject but, in Kant's words (A350), the ‘single common subject’ of a number of representations and the single common agent of various acts of deliberation and action.

This is one of the two forms of unified consciousness that UC(1) does not fit. When one is aware of oneself as the common subject of experiences, the common agent of actions, one is not aware of *a number* of objects. Some think that when one is aware of oneself as subject, one is not aware of oneself as an *object* at all. Kant held this view (A382, A402, B429). Whatever the merits of this view, it is clear that when one is aware of oneself as the single common subject of many representations, one is not aware of a number of things. Rather, one is aware of, and knows that one is aware of, one and the same thing -- via a number of representations. Call this kind of unified consciousness UC(2). Even though UC(2) is different from UC(1), we still have the core idea: unified consciousness consists in tying what is contained in a number of representations, in this case a number of representations of oneself, together so that they are all part of a single field or state or act of consciousness.

Unified consciousness of self has been argued to have some very special properties. In particular, there is a small but important literature on the idea that the reference to oneself as oneself by which one achieves awareness of oneself as subject involves no ‘identification’ (Castañeda, 1966; Shoemaker, 1968; Perry, 1979). Generalizing the notion a bit, some claim that reference to self does not proceed by way of attribution of properties or features to oneself at all. One argument for this view is that one is or could be aware of oneself as the subject of each and every one of one's conscious experiences. If so, awareness of self is not what Bennett calls ‘experience-dividing’ -- statements expressing it have "no direct implications of the form ‘I shall experience C rather than D’" (Bennett, 1974, p. 80). If this is so, the linguistic activities using first person pronouns by which we refer to ourselves as subject and the representational states that result have to have some unusual properties.

2.4 Unity of focus

Finally, as we said, we need to distinguish a fourth site of unified consciousness. Let us call it unity of focus. Unity of focus is our ability to pay unified *attention* to objects, one's representations, and one's own self. It is different from the other sorts of unified consciousness. In the other three situations, consciousness ranges over either many objects or many instances of consciousness of an object (in unified consciousness of oneself). Unity of focus picks out one such item (or a small number of them). Wundt captures what I have in mind well in his distinction between the field of consciousness *(Blickfeld)* and the focus of consciousness *(Blickpunkt).* The consciousness of a single item on which one is focusing is unified because one is aware of many aspects of the item in one state or act of consciousness (especially relational aspects, e.g., any dangers it poses, how it relates to one's goals, etc.) and one is aware of many different considerations with respect to it in one state or act of consciousness (goals, how well one is

achieving them with respect to this object, etc.). UC(1) does not fit this kind of unified consciousness any better than it fit unified consciousness of self. Here too we are not, or need not be, aware of a *number* of items. Rather, one is integrating a number of *properties* of an item, especially properties that involve *relationships* to oneself, and integrating a number of one's *abilities* and applying them to the item, and so on. Call this form of unified consciousness UC(3). One way to think of the relationship of UC(3) (unified focus) to UC(1) and UC(2) is this. UC(3) occurs *within* UC(1) and UC(2) -- within unified consciousness of world and self.

Though this has often been overlooked, all forms of unified consciousness come in both simultaneous and across-time versions. That is to say, the unity can consist in links of certain kinds among phenomena occurring at the same time (synchronically) and it can consist in links of certain kinds among phenomena occurring at different times (diachronically). In its synchronic form, it consists in such things as our ability to compare items to one another, for example, to see if an item fits into another item. Diachronically, it consists in a certain crucial form of memory, namely, our ability to retain a representation of an earlier object in the right way and for long enough to bring it as recalled into current consciousness of currently represented objects in the same as we do with simultaneously represented objects. Though this process across time has always been called the unity of consciousness, sometimes even to the exclusion of the synchronic unity just delineated, another good name for it would be *continuity of consciousness.* Note that this process of relating earlier to current items in consciousness is more than, and perhaps different from, the learning of new skills and associations. Even severe amnesiacs can do the latter.

That consciousness can be unified across time as well as at a given time points up just how central unity of consciousness is to cognition. Without the ability to retain representations of earlier objects and unite them with current represented objects, most complex cognition would simply be impossible. The only bits of language that one would be able to understand, for example, would be single words; the simplest of sentences is an entity spread over time. Now, unification *in consciousness* might not be the only way to unite earlier cognitive states (earlier thoughts, earlier experiences) with current ones but it is certainly a central way and the one best known to us. The unity of consciousness is central to cognition.

2.5 Other Forms of Unity

We will close this section by noting that UC(1), UC(2) and UC(3) are not the only kinds of mental unity. Our remarks about UC(3), specifically about what can be integrated in focal attention, might already have suggested as much. There is unity in the exercise of our cognitive capacities, unity that consists of integration of motivating factors, perceptions, beliefs, etc., and there is unity in the outputs, unity that consists of integration of behavior.

Human beings bring a strikingly wide range of factors to bear on a cognitive task such as seeking to characterize something or trying to reach a decision about what to do about something. For example, we can bring to bear: what we want; what we believe; our attitudes to self, situation, and context; input from each of our various senses; information about the situation, other people, others' beliefs, desires, attitudes, etc.; the resources of however many languages we have available to us; various kinds of memory; bodily

sensations; our various and very diverse problem-solving skills; and so on. Not only can we bring all these elements to bear, we can integrate them in a way that is highly structured and ingeniously appropriate to our goals and the situation(s) before us. This form of mental unity could appropriately be called *unity of cognition.* Unity of consciousness often goes with unity of cognition because one of our means of unifying cognition with respect to some object or situation is to focus on it consciously. However, there is at least some measure of unified cognition in many situations of which we are not conscious, as is testified by our ability to balance, control our posture, manoeuver around obstacles while our consciousness is entirely absorbed with something else, and so on.

At the other end of the cognitive process, we find an equally interesting form of unity, what we might call *unity of behavior,* our ability to coordinate our limbs, eyes, bodily attitude, etc. The precision and complexity of the behavioral coordination we can achieve would be difficult to exaggerate. Think of a concert pianist performing a complicated work.

3. Empirical Phenomena Related to Unified Consciousness

One of the most interesting ways to study psychological phenomena is to see what happens when they or related phenomena break down. Phenomena that look simple and seamless when functioning smoothly often turn out to have all sorts of structure when they begin to malfunction. Like other psychological phenomena, we would expect unified consciousness to be open to being damaged, distorted, etc., too. And if the unity of consciousness is as important to cognitive functioning as we have been suggesting, such damage or distortion should create serious problems for the people to whom it happens. The unity of consciousness is damaged and/or distorted in both naturally-occurring and experimental situations, and some of these situations are indeed very serious for those undergoing them.

In fact, unified consciousness can break down in what look to be two distinct ways. There are situations in which it is natural to say that one unified conscious being has split into two unified conscious beings without the unity itself being destroyed or even significantly damaged, and situations in which at all times we have one being with one instance of consciousness but the unity itself appears to be damaged or even destroyed. In the former cases, there is reason to think that a single instance of unified consciousness has become two (or something like two). In the latter cases, unity of consciousness has been compromised in some way but nothing suggests that anything has split.

3.1 Split Consciousness

First, situations in which we are inclined to say that something has split. Some such description seems natural in at least three different kinds of situation.

(1) Brain Bisection Operations

One is ‘brain bisection’ operations (commissurotomies), specifically certain results of them. In these operations, the corpus callosum is cut to stop the spread of epileptic seizures from one hemisphere to the other. The corpus callosum is a large strand of about 200,000,000 neurons running from one hemisphere to the other. When present, it is the chief channel of communication between the hemispheres. These operations, done mainly in the 1960s, were a last-ditch effort to control certain kinds of severe epilepsy by stopping seizures in one lobe of the cerebral cortex from spreading to the other lobe. Under certain laboratory conditions, two ‘centers of consciousness’ seem to appear in patients who have had this operation (Nagel, 1971; Marks, 1981). Here is a couple of examples of the kinds of behavior that prompt such an assessment.

The human retina is split vertically in such a way that the left half of the retina is primarily hooked up to the left hemisphere of the brain and the right half of the retina is hooded up to the right hemisphere of the brain. Now suppose that we flash the word TAXABLE on a screen in front of a brain bisected patient in such a way that the letters TAX hit one side of the retina, the letters ABLE the other and we put measures in place to ensure that the information hitting each retina stays in one lobe and is not fed to the other. If such a patient is asked what word is being shown, the mouth will say TAX while the hand controlled by the hemisphere that does not control the mouth (usually the left hand) will write ABLE. Or, if the hemisphere that controls a hand is asked to do arithmetic in a way that does not penetrate to the hemisphere that controls the mouth and the hands are shielded from the eyes, the mouth will insist that it is not doing arithmetic, has not even thought of arithmetic today, etc., -- while the appropriate hand is busily doing arithmetic! Notice that since the two ‘centers’ coexist and are active at the same time, whatever breach of unified consciousness there is in these cases is a breach of synchronically unified consciousness. These operations have received a huge amount of attention from philosophers in the past few decades and we will return to them.

(2) Hemi-neglect

Another phenomenon where we may find something like a split without diminished or destroyed unity is hemi-neglect, the strange phenomenon of losing all sense of one side of one's body or sometimes a part of one side of the body. Whatever it is exactly that is going on in hemi-neglect, unified consciousness remains. It is just that its ‘range’ has been bizarrely circumscribed. It ranges over only half the body (in the most common situation), not seamlessly over the whole body. Where we expect proprioception and perception of the whole body, in these patients they are of (usually) only one-half of the body.

(3) Dissociative Identity Disorder

A third candidate phenomenon is what used to be called Multiple Personality Disorder, now, more neutrally, Dissociative Identity Disorder (DID). Everything about this phenomenon is controversial, including whether there is any real multiplicity *of consciousness* at all, but one common way of describing what is going on in at least some central cases is to say that the units (whether we call them persons, personalities, sides of a single personality, or whatever) ‘take turns’, usually with pronounced changes in personality. When one is active, the other(s) usually is(are) not. If this is an accurate description, then here

too we have a breach in unity of some kind in which unity is nevertheless not destroyed. Notice that whereas in brain bisection cases the breach, whatever it is like, is synchronic (at a time), here it is diachronic (across time), different unified ‘packages’ of consciousness taking turns, and the breach consists primarily in some pattern of reciprocal (or sometimes one way) amnesia -- some pattern of each ‘package’ not remembering having the experiences or doing the things had or done when another ‘package’ was in charge.

3.2 Shattered Consciousness

By contrast to brain bisection and DID cases, there are phenomena in which unified consciousness does not seem to split and does seem to be damaged or even destroyed altogether. In brain bisection and dissociative identity cases, the most that is happening is that unified consciousness is splitting into two or more relatively intact units -- two or more at a time or two or more across time. It is a matter of controversy whether even that is happening, especially in DID cases, but we clearly do not have more than that. In particular, the unity itself does not disappear; while it may split, we could say, it does not shatter. There are at least three kinds of case in which unity does appear to shatter.

(1) Schizophrenia

One is some particularly severe forms of schizophrenia. Here the victim seems to lose the ability to form an integrated, interrelated representation of his or her world and his or her self altogether. The person speaks in ‘word salads’ that never get anywhere, indeed sometimes never become complete sentences. The person is unable to put together integrated plans of actions even at the level necessary to obtain sustenance, tend to bodily needs, or escape painful irritants. And so on. Here, it seems more correct to say that unity of consciousness has shattered than split. The behavior of these people seems to express no more than what we might call experience-fragments, each lasting a tiny length of time and unconnected to any others. In particular, except for the (usually semantically irrelevant) associations that lead these people from each entry to the next in the word salads they create, to be aware of one of these states is not to be aware of any others -- or so the evidence suggests.

(2) Dysexecutive Syndrome

In schizophrenia of this sort, the shattering of unified consciousness is part of a general breakdown or deformation of mental functioning: affect, desire, belief, even memory all suffer massive distortions. In another kind of case, the normal unity of consciousness seems to be just as absent but there does not seem to be general disturbance of the mind. This is what some researchers call dysexecutive syndrome (Dawson, 1998, p. 215). What characterizes the breakdown in the unity of consciousness here is that subjects are unable to consider two things together, even things that are directly related to one another. For example, such people cannot figure out whether a piece of a puzzle fits into a certain place even when the piece and the puzzle are both clearly visible and the piece obviously fits. They cannot crack an egg into a pan. And so on.

(3) Simultagnosia

A disorder presenting similar symptoms is simultagnosia or Balint's syndrome (Balint was an earlier 20th century German neurologist). In this disorder, which is fortunately rare, patients see only one object located at one ‘place’ in the visual field at a time. Outside of a few ‘degrees of arc’ in the visual field, these patients say they see nothing and seem to be receiving no information (Hardcastle, in progress). In both dysexecutive disorder and simultagnosia (if we have two different phenomena here), subjects seem not to be aware of even two items in a single conscious state.

We can pin down what is missing in each case a bit more precisely. Recall the distinction between being conscious of individual objects and having unified consciousness of a number of objects at the same time introduced at the beginning of this article. Broadly speaking, we can think of the two phenomena isolated by this distinction as two stages. First, the mind ties together various sensory inputs into representations of objects. In contemporary cognitive research, this activity has come to be called binding (Hardcastle 1998 is a good review). Then, the mind ties these represented objects together to achieve unified consciousness of a number of them at the same time. (The first theorist to separate these two stages was Kant, in his doctrine of synthesis.) The first stage continues to be available to dysexecutive and simultagnosia patients: they continue to be aware of individual objects, events, etc. The damage seems to be to the second stage: it is the tying of objects together in consciousness that is impaired or missing altogether. The distinction can be made this way: these people can achieve some UC(S), unity of focus with respect to individual objects, but little or no unified consciousness of any of the three kinds over a number of objects.

The same distinction can also help make clear what is going on in the severe forms of schizophrenia just discussed. Like dysexecutive syndrome and simultagnosia patients, severe schizophrenics lack the ability to tie represented objects together, but they also seem to lack the ability to form unified representations of individual objects. In a different jargon, these people seem to lack even the capacity for object constancy. Thus their cognitive impairment is much more severe than that experienced by dysexecutive syndrome and simultagnosia patients.

With the exception of brain bisection patients, who do not evidence distortion of consciousness outside of specially contrived laboratory situations, the split or breach occurs naturally in all the patients just discussed. Indeed, they are a central class of the so-called ‘experiments of nature’ that are the subject-matter of contemporary neuropsychology. Since all the patients in whom these problems occur naturally are severely disadvantaged by their situation, this is further evidence that the ability to unify the contents of consciousness is central to proper cognitive functioning.

3.3 What Happens When Unified Consciousness Breaks Down?

Is there anything common to the six situations of breakdown in unified consciousness just sketched? And how do they relate to UC(1), UC(2) or UC(3)?

In brain bisection cases, the key evidence for a duality of some kind is that there are situations in which whatever is aware of some items being represented in the body in question is not aware of other items being represented in that same body at the same time. We looked at two examples of the phenomenon in Section 3 in connection with the word TAXABLE and the doing of arithmetic. With respect to these represented items, there is a significant and systematically extendable situation in which to be aware of some of these items is *not* to be aware of others of them. This seems to be what motivates the judgment in us that these patients evidence a split in unified consciousness. If so, brain bisection cases are a straightforward case of a failure to meet the conditions for UC(1). However, they are more than that. Because the ‘centers of consciousness’ created in the lab do not communicate with one another except in the way that any mind can communicate with any other mind, there is also a breakdown in UC(2). One subject of experience aware of itself as the single common subject of its experience seems to become two (in some measure at least).

In DID cases, a central feature of the case is some pattern of amnesia. Again, this is a situation in which being conscious of some represented objects goes with not being conscious of others in a systematic way. The main difference is that the breach is at a time in brain bisection cases, across time in DID cases. So again the breakdown in unity consists in a failure to meet the conditions for UC(1). However, DID being diachronic, there is also a breakdown in UC(2) across time -- though there is continuity across time within each personality, there seems to be little or no continuity, conscious continuity at any rate, from one to another.

The same pattern is evident in the cases of severe schizophrenia, dysexecutive disorder and simultagnosia that we considered. In all three cases, consciousness of some items goes with lack of consciousness of others. In these cases, to be aware of a given item is precisely *not* to be aware of other relevant items. However, in the severe schizophrenia cases we considered, there is also a failure to meet the conditions of UC(3).

Hemi-neglect is a bit different. Here we do not have two or more ‘packages’ of consciousness and we do not have individual conscious states that are not unified with other conscious states. (Not so far as we know -- for there to be conscious states not unified with the states on which the patient can report, there would have to be consciousness of what is going on in the side neglected by the subject with whom we can communicate and there is no evidence for this.) Here none of the conditions for UC(1), UC(2) or UC(3) fail to be met -- but that may be because hemi-neglect is not a *split or a breakdown* in unified consciousness in the first place. It may be simply a shrinking of the range of phenomena over which otherwise intact unified consciousness extends.

It is interesting that none of the breakdown cases we have considered evidence damage to or destruction of the unity in UC(2). We have seen cases in which unified consciousness it might split at a time (brain bisection cases) or over time (DID cases) but not cases in which the unity itself is significantly damaged or destroyed. Nor is our sample unrepresentative; the cases we have considered are the most widely discussed cases in the literature. There do not seem to be many cases in which it is plausible to say that UC(2), awareness of oneself as a single common subject, has been damaged or destroyed.

4. Recent Philosophical Work

4.1 The Kantian Approach

After a long hiatus, serious work on the unity of consciousness began in recent philosophy with two books on Kant, P. F. Strawson (1966) and Jonathan Bennett (1966). Both of them had an influence far beyond the bounds of Kant scholarship. (A second book by Bennett (1974) should also be mentioned). Central to these works is an exploration of the relationship between unified consciousness, especially unified consciousness of self, and our ability to form an integrated, coherent representation of the world, a linkage that the authors took to be central to Kant's transcendental deduction of the categories. Whatever the merits of the claim (see Brook 1994 for a skeptical judgment), their work set off a long line of writings on the supposed link. Sydney Shoemaker (1984 and 1996), Karl Ameriks (1983), Paul Guyer (1987), Patricia Kitcher (1990), and Quassim Cassam (1997) are some of the philosophers who have worked on unified consciousness from a broadly Kantian point of view. Quite recently the approach prompted a debate about unity and objectivity among Michael Lockwood, Susan Hurley and Anthony Marcel in Peacocke (1994) (note that ‘unity of consciousness’ even occurs in the book's title).

4.2 Philosophical Reflections on Brain Bisection Operations

Another issue that led philosophers back to the unity of consciousness, perhaps the next historically, was the neuropsychological results of brain bisection operations that we explored earlier. Starting with Thomas Nagel (1971) and continuing in the work of Charles Marks (1981), Derek Parfit (1971 and 1984), Lockwood (1989), Hurley (1998) and many others, these operations have been a major theme in work on the unity of consciousness since the 1970s. Much ink has been spilled on the question of what exactly is going on in the phenomenology of brain bisection patients. Nagel goes so far as to claim that there is no whole number of ‘centers of consciousness’ in these patients: there is too much unity to say "two", yet too much splitting to say "one".

Some recent work by Jocelyne Sergent (1990) might seem to support this conclusion. She found, for example, that when a sign ‘6’ was sent to one hemisphere of the brain in these subjects and a sign ‘7’ was sent to the other in such a way that crossover of information from one hemisphere to the other was extremely unlikely, they could say that the 6 is a smaller number than the 7 but could not say whether the signs were the same or different. It is not certain that Sergent's work does support Nagel's conclusions. First, Sergent's claims are controversial -- not all researchers have been able to replicate them. Second, even if the data are good, the interpretation of them is far from straightforward. In particular, they seem to be consistent with there being a clear answer to any *precise* ‘one or two?’ question that we could ask. (’Unified consciousness of the two signs with respect to numerical size?’ Yes. ‘Unified consciousness of the visible structure of the signs?’ No). If so, it is not obvious that the fact that there is mixed evidence, some pointing to the conclusion ‘one’, some pointing to the conclusion ‘two’, supports the view expressed by Nagel that there may be no whole number of subjects that these patients are.

Much of the work since Nagel has focused on the same issue of the kind of split that the laboratory manipulations of brain bisection patients induces. Some attention has also been paid to the implications of these splits. For example, could one hemisphere commit a crime in such a way that the other could not justifiably be held responsible for it? Or, if such splitting occurred regularly and was regularly followed by merging with ‘halves’ from other splits, what would the implications be for our traditional notion of what philosophers call ‘personal identity’, namely, being or remaining one and the same thing. (Here we are talking about identity in the philosopher's sense of being or remaining one thing, not in the sense of the term that psychologists use when they talk of such things as ‘identity crises’.)

Parfit has made perhaps the largest contributions to the issue of the implications of brain bisection cases for personal identity. Phenomena relevant to identity in things others than persons can be a matter of degree. This is well illustrated by the famous ship of Theseus example. Suppose that over the years, a certain ship in Theseus was rebuilt, board by board, until every single board in it has been replaced. Is the ship at the end of the process the ship that started the process or not? Now suppose that we take all those rotten, replaced boards and reassemble them into a ship? Is *this* ship the original ship of Theseus or not? Many philosophers have been certain that such questions cannot arise for persons ; identity in persons is completely clear and unambiguous, not something that could be a matter of degree as related phenomena obviously can be with other objects (Bishop Joseph Butler [1736] is a well-known example). As Parfit argues, the possibility of persons (or at any rate minds) splitting and fusing puts real pressure on such intuitions about our specialness; perhaps the continuity of persons can be as partial and tangled as the continuity of other middle-sized objects.

Lockwood's exploration of brain bisections cases goes off in a different direction, two different directions in fact (we will examine the second below). Like Nagel, Marks, and Parfit, Lockwood has written on the extent to which what he calls ‘co-consciousness’ can split. (’Co-consciousness’ is the term that many philosophers now use for the unity of consciousness; roughly, two conscious states are said to be co-conscious when they are related to one another as conscious states are related to one another in unified consciousness.) He also explores the possibility of psychological states that are not determinately in any of the available ‘centers of consciousness’ and the implications of this possibility for the idea of the specious present, the idea that we are directly and immediately aware of a certain tiny spread of time, not just the current infinitesimal moment of time. He concludes that the determinateness of psychological states being in an available ‘center of consciousness’ and the notion that psychological states spread over at least a small amount of time in the specious might well present stand or fall together.

4.3 Hurley on the Unity of Consciousness

Some philosophers interested in pathologies of unified consciousness examine more than brain bisection cases. In what is perhaps the most complex work on the unity of consciousness to date, Hurley examines most of the kinds of breakdown phenomena that we introduced earlier. She starts with an intuitive notion of co-consciousness that she does not formally define. She then explores the implications of a wide range of ‘experiments of nature’ and laboratory experiments for the presence or absence of co-consciousness across the psychological states of a person. For example, she considers acallosal patients (people born without a corpus callosum). When present, the corpus callosum is the chief channel of communication

between the hemispheres. When it is cut, it is possible to generate what looks like two centers of consciousness, two internally co-conscious systems that are not co-consciousness with one another. (We examined the kind of evidence that leads to this appearance in Section 3.) Hurley argues that in patients in whom it never existed, things are not so clear. Even though the channels of communication in these patients are often in part external (behavioral cuing activity, etc.), the result may still be a single co-conscious system. That is to say, the neurological and behavioral basis of unified consciousness may be very different in different people.

Hurley also considers research by Trewarthen in which a patient is conscious of some object seen by, say, the right hemisphere until her left hand, which is controlled by the right hemisphere, reaches for it. Somehow the act of reaching for it seems to obliterate the consciousness of it. Very strange -- how can something pop into and disappear from unified consciousness in this way? This leads her to consider the notion of *partial unity*. Could two centers of consciousness, A and B, though not co-conscious with one another, nonetheless both be co-conscious with some third thing, e.g., the volitional system B (the system of intentions, desires, etc.). If so, ‘co-conscious’ is not a transitive relationship -- A could be co-conscious with B and C could be co-conscious with B without A being co-conscious with C. This is puzzling enough. Even more puzzling would be the question of how activation of the system B with which both A and C are co-conscious could result in either A or C ceasing to be conscious of an object aimed at by B.

Hurley's response to Trewarthen's cases (and also Sergent's cases that we examined in the previous section) is to accept that intention can obliterate consciousness and then distinguish time periods (1998, p. 216). At any given time in Trewarthen's cases, the situation with respect to unity is clear. That the picture does not conform to our usual expectations for diachronic singularity or transitivity then becomes simply an artefact of the cases, not a problem. It is not made clear how this reconciles Sergent's evidence with unity. One strategy would be the one we considered earlier: make the questions more precise. For precise questions, there seems to be a coherent answer about unity for every phenomenon Sergent describes.

Hurley also considers what she calls Marcel's case. Here subjects are asked to report the appearance of some item in consciousness in three ways at the same time -- say, by blinking, pushing a button, and saying, ‘I see it’. Remarkably, any of these acts can be done without the other two. And the question is, What does this imply for unified consciousness? In a case in which the subject pushes the button but neither blinks nor says anything, for example, is the hand-controller aware of the object while the blink-controller and the speech-controller are not? How could the conscious system become fragmented in such a way?

Hurley's suggestion is: they can't. What induces the appearance of incoherence about unity is the short time scale. Suppose that it takes some time to achieve unified consciousness, perhaps because some complex feedback processes are involved. If that were the case, then we do not have a stable unity situation in Marcel's case. The subjects are not given enough time to achieve unified consciousness of any kind (1998, p. 216).

There is a great deal more to Hurley's work. She urges, for example, that there a normative dimension to unified consciousness -- conscious states have to cohere for unified consciousness to result. And systems

in the brain have to achieve she calls ‘dynamic singularity’ -- being a single system -- for unified consciousness to result.

4.4 The Binding Problem

A third issue that got philosophers working on the unity of consciousness again is binding (again, see Hardcastle's 1998 review). Here the connection is more distant because binding as usually understood is not unified consciousness as we have been discussing it. Recall the two stages of cognition laid out earlier. First, the mind ties together various sensory inputs into representations of objects. Then the mind ties these represented objects to one other to achieve unified consciousness of a number of them at the same time. It is the first stage that is usually called binding. The representations that result at this stage need not be conscious in any of the ways delineating earlier -- many perfectly good representations affect behavior and even enter memory without ever becoming conscious. Representations resulting from the second stage need not be conscious, either, but when they are, we have at least some of the kinds of unified consciousness delineated in Section 2.

4.5 Neurophysiology and the Unity of Consciousness

In the past few decades, philosophers have also worked on how unified consciousness relates to the brain. Lockwood, for example, thinks that relating consciousness to matter will involve more issues on the side of matter than most philosophers think. (We mentioned that his work goes off in two new directions. This is the second one.) Quantum mechanics teaches us that the way in which observation links to physical reality is a subtle and complex matter. Lockwood urges that our conceptions will have to be adjusted on the side of matter as much as on the side of mind if we are to understand consciousness as a physical phenomenon and physical phenomena as open to conscious observation. If it is the case not only that our understanding of consciousness is affected by how we think it might be implemented in matter but also that processes of matter are or can be affected by our (conscious) observation of them, then our picture of consciousness stands as ready to affect our picture of matter as vice-versa.

The Churchlands, Paul M. and Patricia S. (see for example P. M. Churchland 1995, p. 214), and Daniel Dennett (1991) have fairly radical views of the underlying architecture of unified consciousness. The Churchlands see unity itself much as other philosophers do. They do argue that the term ‘consciousness’ covers a range of different phenomena that need to be distinguished from one another but the important point here is that they urge that the architecture of the underlying processes probably consist not of transformations of symbolically encoded objects of representations, as most philosophers have believed, but of vector transformations in what are called phase spaces. Dennett articulates an even more radical view, encompassing both unity and underlying architecture. For him, unified consciousness is simply a temporary ‘virtual captain’, a small group of related information-parcels that happens to gain temporary dominance in a struggle for control of such cognitive activities as self-monitoring and self-reporting in the vast array of microcircuits of the brain. We take these transient phenomena to be more than they are because each of them is the ‘me’ of the moment; the temporary coalition of conscious states winning at the moment is what I am, is the self. Radical implementation, narrowed range and transitoriness

notwithstanding, when unified consciousness is achieved, these philosophers tend to see it in the way we have presented it.

Dennett's and the Churchlands' views fit naturally with a dynamic systems view of the underlying neural implementation. The dynamic systems view is the view that unified consciousness is a result of certain self-organizing activities in the brain. Dennett thinks that given the nature of the brain, a vast assembly of neurons receiving electrochemical signals from other neurons and passing such signals to yet other neurons, cognition could not take any form other than something like a pandemonium of competing bits of content, the ones that win the competition being the ones that are conscious. The Churchlands don't tend to agree with Dennett about this. They see consciousness as a state of the brain, the ‘wetware’, not a result of information processing, of ‘software’. They also advocate a different picture of the underlying neurological process. As we said, they think that transformations of complex vectors in a multi-dimensional phase space are the crucial processes, not competition among bits of content. However, they agree that it is very unlikely that the processes that subserve unified consciousness are sentence-like or language-like at all. It is too early to say whether these radically novel pictures of what the system that implements unified consciousness is like will hold any important implications for what unified consciousness is or when it is present.

Hurley is also interested in the relationship of unified consciousness to brain physiology. It would be truer to say of her that she resists certain standard ways of linking them, however, than to say that she herself links them. In particular, while she clearly thinks that physiological phenomena have all sorts of implications and give rise to all sorts of questions about the unity of consciousness, she strongly resists any simplistic patterns of connection. Many researchers have been attracted by some variant of what she calls the *isomorphism hypothesis*. This is the idea that changes in consciousness will parallel changes in brain structure or function. She wants to insist, to the contrary, that often two instances of exactly the same change in consciousness will go with very different changes in the brain. We saw an example in the last section. In most of us, unified consciousness is closely linked to an intact, functioning corpus callosum. However, in acallosal people, there may be the same unity but achieved by mechanisms such as cuing activity external to the body that are utterly different from communication though a corpus callosum. Going the opposite way, different changes in consciousness can go with the same changes to structure and function in the brain.

4.6 Other Work

Two philosophers have gone off in directions different from any of the above, Stephen White (1991) and Christopher Hill (1991). White's main interest is not the unity of consciousness as such but what one might call the unified locus of responsibility -- what it is that ties something together to make it a single agent of actions, i.e., something to which attributions of responsibility can appropriately be made. He argues that unity of consciousness is one of the things that go into becoming unified as such an agent but not the only thing. Focused coherent plans, a continuing single conception of the good, reasonably good autobiographical memory, certain future states of persons mattering to us in a special way (mattering to us because we take them to be future states of ourselves, one would say if it were not blatantly circular), a certain continuing kind and degree of rationality, certain social norms and practices, and so on and so

forth. In his picture of moral responsibility, unbroken unity of consciousness at and over time is only a small part of the story.

Hill's fundamental claim is that a number of different relationships between psychological states have a claim to be considered unity relationships, including: being owned by the same subject, being [phenomenally] next to (and other relationships that states in the field of consciousness appear to have to one another), both being the object of a single other conscious state, and jointly having the appropriate sorts of effects (functions). An interesting question, one that Hill does not consider, is whether all these relations are what interests us when we talk about the unity of consciousness or only some of them (and if only some of them, which ones). Hill also examines scepticism about the idea that clearly bounded individual conscious states exist. Since we have been assuming throughout that such states do exist, it is perhaps fortunate that Hill argues that we could safely do so.

In some circles, the idea that consciousness has a special kind of unity has fallen into disfavor. Nagel (1971), Donald Davidson (1982), and Dennett (1991) have all urged that the mind's unity has been greatly overstated in the history of philosophy. The mind, they say, works mostly out of the sight *and the control* of consciousness. Moreover, even states and acts of ours that are conscious can fail to cohere. We act against what we know perfectly well to be our own most desired course of action, for example, or do things while telling ourselves that we must avoid doing them. There is an approach to the small incoherencies of everyday life that does not requires us to question whether consciousness is unified in this way, the Freudian approach (e.g., Freud 1916/17). This approach accepts that the unity of consciousness exists much as it presents itself but argues that the range of material over which it extends is much smaller than philosophers once thought. This latter approach has some appeal. If something is out of sight and/or control, it is out of the sight or control of what? The answer would seem to be, the unified conscious mind. If so, the only necessary difference between the pre-twentieth century vision of unified consciousness as ranging over everything in the mind and our current vision of unified consciousness is that the range of psychological phenomena over which unified consciousness ranges has shrunk.

A final historical note. At the beginning of the 21st century, work on the unity of consciousness continues apace. For example, a major conference was recently devoted to the unity of consciousness, the *Association for the Scientific Study of Consciousness Conference* held in Brussels in 2000 *(ASSC5)* Encyclopedias of philosophy (such as this one) and of cognitive science are commissioning articles on the topic. Psychologists are taking up the issue. Bernard Baars (1988, 1997) notion of the global workspace is an example. Another example is work on the role of unified consciousness in precise control of attention. However, the topic is not yet at the center of consciousness studies. One illustration of this is that it can still be missing entirely in anthologies of current work on consciousness.

5. A Background Question

We will close with a different issue. As we saw, philosophers used to think that the unity of consciousness has huge implications for the nature of the mind, indeed entails that the mind could not be made out of matter. We also saw that the prospects for this inference are not good. What about the *nature* of

consciousness? Does the unity of consciousness have any implications for this issue?

There are currently at least three major camps on the nature of consciousness. One camp sees the ‘felt quality’ of representations as something quite unique, in particular as quite different from the power of representations to change other representations and shape belief and action. On this picture, representations could function much as they do without it being like anything to have them. They would merely not be conscious. If so, consciousness may not play any important cognitive role at all, its unity included (Jackson 1986; Chalmers 1996). A second camp holds, to the contrary, that consciousness is simply a special kind of representation (Rosenthal 1991; Dretske 1995; Tye 1995). And a third holds that what we label ‘consciousness’ is really something else. On this view, consciousness will in the end be ‘analyzed away’ -- the term is too coarse-grained and presents things in too unquantifiable a way to have any use in a mature science of the mind (P. S. Churchland 1983).

It is not obvious that the unity of consciousness has strong implications for the truth or falsity of any of these views. If it is as central and undeniable as many have suggested (we saw some of the arguments earlier), its existence may cut against the third, eliminativist position a bit. With respect to the other two positions, the unity of consciousness seems neutral.

Whatever its implications for other issues, the unity of consciousness seems to be a real feature of the human mind, indeed central to it. If so, any complete picture of the mind will have to provide an account of it. Even those who hold that the extent to which consciousness is unified has been overrated owe us an account of *what* has been overrated.

Mental Imagery

Mental imagery (sometimes colloquially called visualization, or "seeing in the mind's eye") is experience that resembles perceptual experience, but which occurs in the absence of the appropriate stimuli for the relevant perception (cf. Finke, 1989; McKellar, 1957). Very often these experiences are understood by their subjects as echoes or reconstructions of actual perceptual experiences from their past; at other times they may seem to anticipate possible, often desired or feared, future experiences. Thus imagery has often been believed to play a very large, even pivotal, role in both memory (Yates, 1966; Paivio, 1986) and motivation (McMahon, 1973). It is also commonly believed to be centrally involved in visuo-spatial reasoning and inventive or creative thought. Indeed, it has usually been regarded as crucial for *all* thought processes, although, during the 20th century in particular, this has been called into question.

1. Terminological and Definitional Problems

We have defined mental imagery as a form of experience, but, of course, evidence for the occurrence of any experience is necessarily subjective. Because of this, some authors, most notably the arch-behaviorist J.B. Watson (1913a), have cast doubt on the scientific status and even the existence of imagery. However, if imagery serves certain functions in our mental life (as suggested above) then perhaps some

objective validation and study of it might be possible through the study of the performance of these functions. In the light of this, some authors (notably the psychologist Stephen Kosslyn, who is probably the most influential contemporary imagery theorist) prefer an alternative definition of "imagery" to that given above. Instead of understanding it primarily as a sort of experience, they prefer to view the term as referring to the particular type of cognitive process or "underlying representation" (Kosslyn, 1983) that is involved in these functions. These representations or processes are generally understood to be such that their presence or activity can (but need not always) be consciously experienced as imagery in our original sense.

However, characterizing imagery in this way (as explanans rather than explanandum) begs important questions about the nature of the mind and about the causes of imagery experiences (conceivably they are *not* experiences of cognitive processes or underlying representations). On the other hand, it should be admitted that defining imagery as a form of experience, is also problematic, and might deflect attention away from the possibility that importantly similar underlying representations or mechanisms may be operative both when we experience imagery *and* during certain unconscious mental processes (some evidence suggests that this is so). To avoid such problems we might replace "imagery" with some special jargon: we could speak of "quasi-perceptual experiences" on the one hand and "image representations (or processes)" on the other. However, this is not an established convention, and using these terms exclusively throughout this entry would seriously complicate discussion of the views of those thinkers (probably the vast majority) who fail to disentangle these notions. Thus, the (more or less) ordinary language term "imagery" will continue to be used where appropriate.

But our initial definition of "imagery" may well be thought unsatisfactory even in its own terms. Not only does it duck the difficult task of specifying what dimensions and degrees of similarity to perception are necessary for an experience to count as imagery; it also elides the controversial question of whether imagery is a *sui generis* phenomenon, conceptually quite distinct from true perceptual experience despite the surface resemblance, or whether it is more appropriately regarded as lying at one end of a continuum stretching from ordinary veridical perception at one end, to ‘pure’ imagery, where the character of the experience seems to be quite independent of any current stimulus input, at the other. In between would come cases, often held to be due to the effects of imagination, where the character of the experience seems to be only *partially* determined by the character of the current stimulus: both mistaken or illusive perception and non-deceptive *seeing as* (such as seeing the notorious duck-rabbit figure *as* a duck [or rabbit], or, for example, "seeing" the shapes of animals, or whatever, in the clouds or constellations). Many philosophers and cognitive theorists implicitly take this line, treating *percepts* as, essentially, special cases of imagery, differing only in causal history and, perhaps, "vivacity". For example: for Descartes (in the *Treatise on Man*) both images and percepts are ultimately embodied as pictures picked out on the surface of the pineal gland by the flow of animal spirits; for Kosslyn (1994) both are depictive representations in the brain's "visual buffer"; for Hinton (1979) both are "structural descriptions" in working memory. However, other theorists (e.g. Sartre, 1936) try to draw a sharp conceptual and phenomenological distinction between perceptual and imaginal experience.

But in the absence of consensus about such issues, or about the underlying mechanisms and the psychological functions of imagery, our initial rough characterization is probably about the best we can

do without begging important questions. Perhaps it is sufficient. Imagery is a common, everyday phenomenon that is indicated by a whole range of colloquial expressions: "having a picture in the head", "picturing", "visualizing", "having/seeing a mental image/picture", "seeing in the mind's eye", and, in some contexts, simply "imagining". Although a small percentage of people seem inclined to deny ever experiencing it, for the vast majority of us, our imagery, like our consciousness itself, is something with which we seem to be thoroughly familiar and intimate.

However, the term "mental imagery", and all the colloquial equivalents mentioned above, may be potentially misleading in itself. For one thing, all these expressions suggest, more or less strongly, a purely visual phenomenon. In fact, most discussions of imagery, in the past and today, have indeed focused upon the visual mode. Nevertheless, there is every reason to believe that other modes of quasi-perceptual experience are just as common and important (Newton, 1982), and "imagery" has come to be the accepted scientific term for referring to them too: interesting studies of "auditory imagery", "kinaesthetic imagery", "haptic (touch) imagery", and so forth, can be found in the contemporary psychological literature.

A related, and perhaps a more serious problem with the term "imagery" and with most of the colloquial alternatives is that they strongly suggest that the phenomenon involves some sort of *picture* (*the image*) entering into or being created in the mind. Indeed, this theoretical story seems to have gone virtually unquestioned during past ages (which may explain how the terminology in question became entrenched), and probably remains the majority, lay and expert, view today. Nevertheless, during this century it has come under strong challenge, and can no longer be regarded as uncontroversial. The confusions arising from this (as well as the other ambiguities of the term "imagery" that we have mentioned) continue to bedevil discussions of the topic. In particular, people who deny the existence of *mental pictures* seem frequently to be misunderstood as (implausibly) denying the occurrence of quasi-perceptual experiences, and in some cases they may themselves come to believe that the first denial commits them to the second (Thomas, 1989). Indeed, there is some reason to think (although it is certainly not established) that that minority of people (about 10% of the population by some estimates) who deny ever experiencing imagery, or who deny that it plays any significant role in their mental lives, may simply be understanding the terminology in a somewhat idiosyncratic fashion: what they intend to deny may not be so much that they *have* quasi-perceptual experience, but, rather, that what they do have is predominantly visual, or that it involves inner pictures, or that it resembles perceptual experience to the extent that they (perhaps wrongly) understand other people to be claiming for *their* imagery (or some combination of these claims). This is a theoretically important issue because if it is true that some people really do not experience any imagery then imagery (understood as experience rather than representation) *cannot* play the vital role in mental life that has very often been attributed to it.

On a more consensual note, with only rare exceptions (e.g. Wright, 1983) nearly all serious discussions of imagery take it for granted (explicitly or implicitly) that it exhibits *intentionality* (i.e. imagery is normally *of* something or other, in the same sense that perception is perception *of* something), and that it is, for the most part, subject to conscious control. Although images often come into the mind unbidden, and sometimes it is hard to shake off unwanted imagery (say, of the horrible accident that one cannot get out of one's mind) in general one can conjure-up, manipulate, and dismiss images at will. In this regard,

imagery appears as an unequivocally *mental* phenomenon, quite distinct from other quasi-perceptual experiences, such as after-images and phosphenes (Oster, 1970), that are *not* subject to direct conscious control, and which are probably best explained in straightforwardly physiological terms. It is also distinguished from cognitive and representational, but nevertheless unconscious and automatic functions such as the postulated high capacity but very short term visual memory store known as "iconic memory" (Neisser, 1967). On the other hand, so called *eidetic imagery*, if, indeed, it exists at all as a distinct phenomenon (see Haber, 1979, and the appended commentaries), is probably best understood as a species of mental imagery proper, despite the fact that it is characterized by a vividness, detailed articulation, and stability that far exceed what most normal subjects seem to want to claim for their imagery experiences.

It may also be worth pointing out that mental imagery should be distinguished from "imagery" as the term has come to be used in a literary context, where it seems to refer to a linguistic trope that employs highly concrete, perceptually specific language in order to evoke certain emotions or otherwise convey some more abstract and elusive underlying sense. Very likely, literary imagery originally got its name from a supposed power of the words in question to induce mental imagery in a reader, and some contemporary literary critics defend such an interpretation (Esrock, 1994; Scarry, 1999), but it is surely not the case that the expression is now universally, or even generally, understood this way.

3. The Eclipse of Imagery in Scientific Psychology

For the late 19th century researchers who established psychology as an empirical scientific discipline, mental images (usually, in English, referred to as *ideas*) held just the same central place in the explanation of cognition that they had held for philosophical psychologists of earlier times. However, developments within psychology at the beginning of the 20th century began to cast doubt on this long established consensus. A group of psychologists working in Würzburg, Germany claimed to have found empirical evidence for conscious thought contents that were not imaginal or perceptual in character. Their results were challenged on several grounds, and were certainly never definitively established. Nevertheless, the bitter dispute that ensued, the so called *imageless thought* controversy, had a profound effect on the development of psychology as a science (and, I would argue, on philosophy also). Most psychologists became, in effect, profoundly disillusioned with the notion of mental imagery, and either avoided seriously considering the topic, treated it dismissively, or, in some extreme cases, denied the existence of the phenomenon outright. These attitudes noticeably influenced other disciplines, including philosophy. Although the psychological study of imagery revived with the rise of cognitivism in the 1960s and 70s, when new experimental techniques were developed that enabled a truly experimental study of the phenomenon, current views about, and attitudes towards, mental imagery cannot be properly understood without an awareness of this history, versions of which, of varying degrees of accuracy, have passed into the folklore of psychology.

3.1 Founders of Experimental Psychology: Wilhelm Wundt and William James

When psychology first began to emerge as an experimental science, in the philosophy departments of the German universities in the late 19th century, the central role of imagery in mental life was not in question. Wilhelm Wundt, acclaimed "the father of experimental psychology", established the first psychological research and teaching laboratory in the Leipzig Philosophy Department in around 1876 (Fancher, 1996). He regarded his psychology as a branch of philosophy, an attempt to apply the experimental method of natural science (particularly, the physiology of Helmholtz) to essentially philosophical problems concerning the nature of mind and its metaphysical status. This view of the subject persisted, in Germany, at least until the Nazi era. Wundt's research program aimed to investigate the "elements of consciousness," and the laws governing the combination of these elements (Wundt, 1912). Although his theoretical system made a place for emotional *feelings* as one class of element, in practice the main focus of Wundt's experimentally based research program was on the elements of *sensation* and their compounding into *ideas*. As has been the case in the empiricist philosophical tradition, these *ideas* were conceived of as, to all intents and purposes, mental images. Indeed, Wundt insists, much in the spirit of Hume, that there is no fundamental difference in kind between the ideas arising directly from perception and "memory images" (Wundt, 1912). Thus, Wundtian experimental psychology was largely a study of cognitive processes, and, for him (and most of his numerous students and imitators), the mental image (under the rubric *idea*) played essentially the same crucial, representational role in cognition that it had played for most of his philosophical predecessors.

Wundt's American counterpart, and contemporary, William James, took a not dissimilar view, although he was careful to acknowledge that in some people the "thought stuff," as he called it, might consist not so much of *visual* imagery as of imagery of other modes, especially the "verbal images" of inner speech (James, 1890 ch. 18). In his textbook *The Principles of Psychology* (1890) James has much that is insightful to say about psychological processes in general, and about the role of imagery in them in particular, but, although he carried out experimental demonstrations in his psychology teaching at Harvard, James had little interest in the actual pursuit of experimental research, and established no graduate teaching program in experimental psychology (Fancher, 1996). Thus, despite the lucidity of his justly famous text, and the wide readership it has continued to find, his direct influence on the disciplinary development of scientific psychology, even in his native America, probably never equaled that of Wundt (or even lesser German pioneers, such as G.E. Müller), who trained many Americans (as well as many Germans, and students of other nationalities) in the techniques of experimental research. Just around this time, when psychology was the latest intellectual fashion, the American Universities were undergoing a tremendous expansion. Thus many of these students were able to return from Germany to the United States to found experimental psychology teaching programs of their own. It was because of this, much more than the intellectual influence of James, that, well before it grew into a dominant world power and achieved its current leadership in the sciences generally, the U.S.A. quickly grew to rival, and eventually surpass, Germany's initial preeminence in scientific psychology.

Although psychologists of this era have often been portrayed (notably by Boring (1950)) as using an introspective methodology, in fact Wundt, in particular, was very sensitive to standard criticisms of introspection, such as the contention that the very attempt to observe our own mental activities will itself alter them. He thus limited its use to situations where he was satisfied that the causes of the relevant

mental events, the experimental stimuli, could be strictly controlled and the results shown to be replicable, with any introspective reports being made unreflectively, as soon as the relevant content appeared in the mind (Mischel, 1970; Danziger, 1980). Wundt's research did *not* rely upon discursive descriptions of mental contents. An "introspective" report in his laboratory might typically have involved no more than indicating the moment when a certain sensation entered consciousness, or saying whether a musical tone seemed higher or lower than the one presented just before. Such "introspective reports" differ little from the sorts of responses that might be called for in a modern cognitive psychology experiment. Wundt's methodological discipline meant that the data collected in his laboratory were primarily such things as reaction times or discrimination thresholds, rather than discursive introspective reports; it also meant, in practice, that his experiments were restricted almost entirely to the study of "lower" psychological processes, principally sensation and perception. Thus, although Wundt did hold that "higher" mental process, such as thought and memory, depended largely upon mental images (including verbal imagery, silent speech), in practice his experimental work did little directly to illuminate these. "Higher" mental processes, for Wundt, were best investigated non-experimentally, via a methodology that he called *völkerpsychologie*, a hermeneutic study of cultural products to which he devoted much of his later career, but which never achieved anything like the influence of his experimentally based work.

3.2 Edward B. Titchener: The Complete Iconophile

An Englishman, Edward B. Titchener, became one of Wundt's most influential students. After graduate studies with Wundt, Titchener moved to the United States and became professor of Psychology at Cornell, where, as well as being responsible for translating many of the more experimentally oriented works of Wundt into English, he established a successful graduate school and a vigorous research program (Tweney, 1987). Despite the fact that Wundt's and Titchener's philosophical and theoretical views, and their scientific methodologies, differed in important ways (Leahey, 1981), Titchener, much more than most of his American born colleagues, shared Wundt's vision of psychology as a pure science, with essentially philosophical rather than pragmatic ends, and he gained the reputation of being Wundt's leading disciple and representative in the English speaking world. However, he had no interest in his master's *völkerpsychologie*. Titchener had been deeply influenced by positivist optimism as to the scope of science, and he hoped to study even the "higher" thought processes experimentally (Danziger, 1979, 1980). Thus he attempted to push the method of controlled laboratory introspection far beyond the bounds that Wundt had so carefully set for it.

Titchener appears to have been both a particularly vivid imager, and a firm believer in imagery's cognitive importance. He had studied British Empiricist philosophy whilst an undergraduate at Oxford, and was well aware of Berkeley's argument that "general ideas" (i.e. mental images that, in-and-of-themselves, represent a kinds or categories of things, rather than particulars) are inconceivable. Berkeley argues that, for instance, the general idea of a triangle, which would need to be:

> neither oblique nor rectangle, neither equilateral, equicrural, nor scalenon, but *all and none* of these at once. In effect it is something imperfect that cannot exist, an idea wherein some

> parts of several different and *inconsistent* ideas are put together. (Berkeley, 1734).

Many philosophers take Berkeley's argument to amount to a knock-down refutation of the traditional theory -- first articulated by Aristotle (*De Interpretatione* 16a; *De Anima* 420b), and reiterated by Locke (1700) -- that images (ideas) are the primary vehicles of thought and that they ground linguistic meaning. If mental images can only, intrinsically represent particulars (as Berkeley, relying on the empiricist view of the nature of imagery as consisting of copies or fading echoes of sensory impressions, argued) then they are surely inadequate for grounding the meanings of the general, categorical terms that are fundamental to thought. However, Titchener, on introspective grounds, flatly rejected Berkeley's claim:

> But I can quite well get . . . the triangle that is no triangle at all and all triangles at one and the same time. It is a flashy thing, come and gone from moment to moment: it hints two or three red angles, with the red lines deepening into black, seen on a dark green ground. It is not there long enough to say whether the angles join to form the complete figure, or even whether all three of the necessary angles are given. Nevertheless, it means triangle; it is Locke's general idea of a triangle; (Titchener, 1909).

Of course, Titchener was well aware that the image described here was thoroughly idiosyncratic. However, he did want to claim that such images (in virtue not so much of their individual, intrinsic characteristics, but of their place in a whole associative network of imagery) do carry meaning, and are thus fitted to be the vehicles of thought. He also described examples of his own visualizations of abstract concepts (such as the concept of *meaning* itself: "the blue-grey tip of a kind of scoop … digging into a dark mass of what appears to be plastic material") and even claimed to experience imaginal meanings of connectives such as *but* (Titchener, 1909). Titchener plainly held that (together with actual sensation) mental content *is* mental imagery.

3.3 The Perky Experiment

Titchener's theories, and, to a very large extent, the introspection based experimental methods he used to test and refine them, have long since fallen into disrepute. (By contrast, Wundt's reputation has seen a considerable revival in recent decades (e.g. Blumenthal, 1975; Bringman & Tweney, 1980; Fancher, 1996).) However, one series of experiments carried out in Titchener's laboratory, by his student C.W. Perky (1910), has achieved something of a classic status in the literature on imagery. Perky asked her subjects to fixate a point on a screen in front of them and to visualize various objects there, such as a tomato, a book, a leaf, a banana, an orange, or a lemon. As the subjects did this, and unbeknownst to them, a faint patch of color, of an appropriate size and shape, and just above the normal threshold of visibility, was back projected (in soft focus) onto the screen. Apart from on a couple of occasions when the projection apparatus was mishandled, none of Perky's subjects (ranging from a ten year old child to her colleagues, the trained and experienced introspectors of Titchener's laboratory) ever realized that they were experiencing real percepts; they took what they "saw" on the screen to be entirely the products of their imagination. In fact, however, the projections did influence their experiences: some subjects expressed surprise at finding themselves imagining a banana "upright" rather than the horizontally

oriented one they had been trying for; one was surprised to wind up imagining an elm leaf after trying for a maple. On the other hand, purely imaginary details were also reported: One subject could "see" the veins of the leaf; another claimed that the title on the imagined book was readable.

Perky's results have been read as evidence that imagery may be systematically confused with genuine visual experience, that images and percepts, as Hume believed, differ subjectively in, at most, only their degree of "vivacity" or vividness. However we should note that the projected color patches were clearly visible as such to people who were not under instructions to form an image (Perky, 1910). Furthermore, Segal (1971b) reports that when she initially tried to replicate the "Perky effect" with "the suspicious, pragmatic students who populated our campuses in the late 1950s and early 1960s," they quickly saw through the deception. Eventually, she achieved better replications by taking steps to induce a state of relaxation in her subjects (Segal & Nathan, 1964). Several subjects, for example, asked to imagine a New York skyline whilst a faint image of a tomato was projected on the screen, reported imagining New York at sunset (Segal, 1972). Nevertheless, Segal concludes, from her extensive experimental studies over many years, that the *Perky effect* arises not so much from the indistinguishability of mental images and (faint) percepts, as from the fact that the effort to form an image, under certain circumstances, interferes with the normal course of perception and raises perceptual detection thresholds (Segal, 1971b; Segal & Fusella, 1971).

3.4 The *Imageless Thought* Controversy

Perhaps Wundt's most important German student was Oswald Külpe, who had for several years served as Wundt's assistant professor, but eventually left to set up his own laboratory in the philosophy department of Würzburg University. He and his students there developed a direct challenge to the prevalent imagery theory of thought. Under the influence of both Machian positivism and, later, the act psychology of Brentano and the phenomenology of Husserl, Külpe, like Titchener (whom he had helped train), rejected what he saw as Wundt's unnecessarily strict methodological restrictions on the scope of empirical science, and encouraged his students to extend the scope of the introspective "experimental" method to the study of the "higher" processes of thought and reasoning (Danziger, 1979, 1980; Ash, 1998). In 1901, two of these students, Mayer and Orth, performed a word association experiment in which subjects were asked to report everything that had passed through their mind between hearing the stimulus word and giving the response. Note that it was normal practice, in this era of psychology, for experimental subjects, or "observers" as they were often called, to be drawn from among fellow researchers within the same laboratory, often including the supervising professor. Present day psychologists would, with good reason, suspect such subjects of being liable to produce results strongly biased by theoretical preconceptions (Orne, 1962; Intons-Peterson, 1983). Great pains are usually taken, today, to ensure that subjects in psychological experiments have no idea what hypothesis the experiment is supposed to be testing. In 1901 however, it was thought that experienced and knowledgeable "observers" were more likely to produce consistent and meaningful results than the psychologically untrained. In the case of the Meyer and Orth experiment, two amongst the four subjects were Meyer and Orth themselves. Nevertheless, they professed to be surprised by some of their findings. In particular:

> The subjects frequently reported that they experienced certain events of consciousness which they could quite clearly designate neither as definite images nor yet as volitions. For example, the subject Meyer made the observation that, in reference to the stimulus word "metre" a peculiar event of consciousness intervened which could not be characterized more exactly, and which was succeeded by the spoken response "trochee".
> (Meyer & Orth, as quoted and translated by Humphrey, 1951)

The jargon term *bewusstseinslagen* ("states of consciousness" -- Humphrey, 1951) was coined to designate these indescribable non-sensorial states, and they soon began to turn up in more and more profusion in the introspective reports generated in the Würzburg laboratory, taking on an increasing theoretical significance as time went by. In 1905 another Würzburg researcher, Ach, also introduced the largely overlapping, but more explicitly intentionalistic concept of *bewusstheit* or "awareness", an unanalysable "impalpably given ’knowing’" (Ach, quoted and translated by Humphrey, 1951), and by 1907, Karl Bühler, perhaps the most radical of Külpe's students, was simply referring to *gedanken* ("thoughts"). Bühler's experiments might, for example, involve giving a subject (often professor Külpe himself) a somewhat gnomic sentence to interpret (e.g. "Thinking is so extraordinarily difficult that many prefer to judge.") and then collecting introspective reports of the conscious, but allegedly non-imaginal, *gedanken* that had occurred between the hearing of the sentence and the giving of the interpretation. Although the Würzburg school never denied that imagery does occur, by this time the greater part of the conscious contents of minds examined in Würzburg seemed to be non-imaginal.

Unsurprisingly, Wundt, and others, refused to accept these new methods and conclusions, and a heated debate, the so called *imageless thought* controversy, ensued. Though Wundt was surely skeptical of the existence of imageless thoughts, his primary criticisms were methodological. He was very much concerned with the fact that the experiments were necessarily constructed so that the introspective reports were given *after* the completion of the experimental task (word association, sentence interpretation, or whatever). The Würzburg research thus involved discursive recollection (or was it reconstruction?) of conscious contents that were no longer present to the mind. Such experiments, Wundt argued, were open invitations to suggestion, and, indeed, were

> not experiments at all in the sense of scientific methodology: they are counterfeit experiments that seem methodical simply because they are ordinarily performed in a psychological laboratory and involve the coöperation of two persons, who purport to be experimenter and observer. In reality, they are as unmethodical as possible; they possess none of the special features by which we distinguish the introspections of experimental psychology from the casual introspections of everyday life. (Wundt, quoted and translated by Titchener, 1909. Original German, 1907.)

Titchener also strongly objected to the *imageless thought* demonstrations, but for different reasons. He did not object to the aims or the introspective methodology of the Würzburg school, but to their purported results, and, for him, the experiments were not so much misconceived as incompetently executed: In particular, he felt, the "observers" (experimental subjects) in Würzburg had been inadequately trained in the art of introspection. According to Titchener, the main pitfall of introspection

was what he called the "stimulus error," the strong tendency to confound the conscious experience itself with whatever it might represent: Thus, to report, when looking at a rectangular table top, that one experiences a rectangle, would be to commit the stimulus error: The "real" conscious content would (on Titchener's view) have the trapezoidal shape that the table top projects upon the retina. For Titchener, the intentionality generally ascribed to *imageless thoughts* only showed that the Würzburg introspectors were systematically committing the stimulus error: They were not reporting the intrinsic nature of their conscious contents, but what those contents signified. Titchener suggested that the purported *bewusstseinslagen* etc. were, in fact, faint and fleeting kinaesthetic sensations, feelings of muscular tension and the like (Tweney, 1987). In his laboratory, experiments quite similar to those done in Würzburg, but carried out using introspective "observers" well trained in avoiding the stimulus error (Titchener himself, or his own graduate students), produced no reports of imageless thoughts. Instead, they found the fleeting imagery or the subtle bodily sensations that Professor Titchener's theory predicted (Titchener, 1909; Humphrey, 1951).

This work of Titchener's (like other responses to the *imageless thought* controversy from America, Britain, and elsewhere) had relatively little impact in Germany, which, with some justification at that time, still regarded itself as very much preeminent in psychological science. Nevertheless, on both sides of the Atlantic the controversy was recognized as touching on deep foundational issues in the science of mind. Although largely forgotten today, it seems to have had a lasting impact on the development not only of psychology, but (especially in the German speaking world, where the fields were more closely intellectually and institutionally entwined) philosophy as well. The Würzburg school's claims, despite their shaky basis, undoubtedly contributed to a sense that imagery could not be so psychologically important as had traditionally been assumed, and that an alternative way of thinking about cognitive content was needed. Many psychologists and philosophers of this era came, partly for this reason, to feel that thought should be understood in terms of language *per se*, and that it was a serious mistake ever to have thought that the representational power of language derives from that of some more fundamental form of representation, such as mental imagery. Bloor (1983) goes so far as to suggest (though without citing any evidence) that the work of the later Wittgenstein largely grew out of the reaction to the *imageless thought* affair. Bloor may be overstating the case, but certainly a leading Würzburg alumnus, Karl Bühler, was established in Vienna during the inter-war years, and Wittgenstein is known to have met him there, and seems to have reacted strongly to his views (Toulmin, 1969; Bartley, 1973). Bühler also taught, and deeply influenced, the young Karl Popper (Popper, 1976), and undoubtedly his views would also have been quite familiar to the Vienna Circle positivists.

But the *imageless thought* controversy was never satisfactorily resolved, at least in the terms in which it was originally posed. Although the Würzburg school has been praised for drawing psychological attention to the intentionality of mental contents, and for the introduction of once important concepts such as "mental set" into psychology, it would certainly be grossly misleading to suggest that their work provides evidence for the existence of non-sensorial conscious mental contents (i.e. imageless thoughts) that comes anywhere close to meeting contemporary scientific standards. Indeed, the fact that Külpe's and Titchener's laboratories each produced results that fitted their directors' contrasting preconceptions did not go unnoticed by their contemporaries. The unresolvable debate contributed significantly to a growing sense of intellectual crisis within psychology, leading to a deep loss of confidence (persisting to

the present) in the scientific value of introspection. It also led to a precipitous decline in scientific interest in imagery. On the one hand its importance in the cognitive economy was now subject to doubt; on the other hand it had come to seem that it was very difficult, if not impossible, to study it experimentally and objectively.

3.5 European Responses: Jaensch, Freud, and Gestalt Psychology

In Germany, some psychologists responded to this crisis by turning away from the experimental study of "cognitive" questions about the workings of the mind in general, and moved instead toward an understanding of their subject as concerned with interpretive studies of persons, or the differences between them. They, generally, became more interested in their subjects' dispositions, values, motives, etc. than in either their imagery (unless, perhaps, its contents were interestingly idiosyncratic) or their *bewusstseinslagen* (if any such existed) (Danziger, 1980).

An exception is the work of Jaensch (1930) on *eidetic* imagery (i.e. visual imagery that is experienced as before the eyes rather than "in the head," and that is unusually vivid and stable -- most evidence for the existence of eidetic imagery comes from studies of children, and it seems to be rare in adults (Haber, 1979)). However, although this work has not been without influence, and is not necessarily entirely devoid of scientific value, it is deeply tainted by Jaensch's enthusiasm for the Nazi racist ideology that was then taking hold in Germany. Eidetic imagery, he claims (on meager evidence), is characteristic of the less developed minds of not only children, but also members of "southern," "sun adapted" (i.e. darker skinned) races. (Jaensch later won notoriety for performing an experiment designed to show that "northern" chickens are racially superior -- as evidenced by more careful and intelligent pecking -- to "southern" ones (Ash, 1998).)

However, the idea that thought processes that rely upon visual imagery (as opposed to verbal thought) are characteristic of minds that are somehow defective or inferior is not confined to Nazi thinkers such as Jaensch in this era. Sigmund Freud (a Jew, who had to flee his native Austria to escape the Nazis) seems implicitly to have regarded visual images reported by his patients as part and parcel of their neuroses, as something to be exorcized and replaced by verbally mediated, "rational" insights (Esrock, 1994 ch. 3). This may well be related to the sensibility that Jay (1993) finds to be pervasive in 20th century French intellectual life, wherein visually based thought and experience is actively disvalued in comparison to other modes of sense experience, and verbally mediated thinking. Arguably, signs of a similar attitude are evident some decades earlier in England, in the responses Francis Galton received to his pioneering questionnaire about mental imagery vividness. Unlike the regular folk he questioned, many of the scientists and other intellectuals amongst Galton's respondents were distinctly unwilling to admit to ever experiencing mental imagery (Galton, 1880, 1883), a finding that more recent research has failed to reproduce (Roe, 1951; and see Ferguson, 1977, 1992; Shepard, 1978a,b; Deutsch, 1981; Miller, 1984). It is hard to say how widespread such attitudes were, or how they originated (or why they now seem to have faded), but they may well have contributed to the sharp decline in intellectual interest in imagery, apparent not only in psychology but also philosophy and literary studies, that is very apparent in the early decades of the 20th century (Esrock, 1994), and which, among philosophers and literary critics at any

rate, has only quite recently shown signs of reversal (e.g. Rollins, 1989; Ellis, 1995; Scarry, 1999).

Many other German psychologists, in the wake of the *imageless thought* controversy, continued to adhere to the Wundtian ambition of developing an experimental science of the mind, and returned to something like the sort of methodological caution in the use of introspective reports that Wundt himself had advocated, often insisting on the direct corroboration of introspective evidence by observable effects on behavior (Danziger, 1980). This usually meant that, as with Wundt himself, although their experimentally based psychology did not explicitly repudiate the essential role traditionally assigned to imagery in thought and memory, in practice it had rather little to say about it. (Plausible behavioral correlates of imagery processes were not established until the rise of the cognitive psychology movement.)

Perhaps the most influential movement arising from this strand of German psychological thought was Gestalt Psychology. It was also perhaps the last German bred movement to make a major impact in the United States, where it became a sort of "official opposition" to the indigenous and dominant Behaviorism. This was facilitated by the fact that, under the pressure of the rising tide of German Naziism, a significant number of Gestalt Psychology's adherents -- including the acknowledged leaders, Max Wertheimer, Wolfgang Köhler, and Kurt Koffka -- emigrated to America during the 1920s and 30s (Ash, 1998). Gestalt Theory attempted to explain "higher" thought processes in terms of a sort of hypothetical neuroscience (*field theory*) rather than in terms of the vicissitudes of introspected thought contents (Thomas, 1987; Ash, 1998). Although the Gestalt psychologists were much concerned with the experimental investigation of subjective experience (from whence they sought most of the evidential support for their views), in practice this research focused almost entirely on *perceptual* experience. The typical Gestaltist experiment sought immediate, unreflective descriptions of the appearance of a carefully constructed stimulus (frequently complex and illusional), and preferentially used subjects naïve to the theoretical views and concerns of the experimenter. This was something very unlike the deliberate "looking within" practiced by the psychologically sophisticated, trained introspectors of Titchener's or Külpe's laboratories. In certain respects Gestalt psychology foreshadowed, and, indeed, importantly influenced, the cognitivist movement of recent decades (Gardner, 1987). Nevertheless, it had little directly to say about the nature or function of imagery.

3.6 The American Response: Behaviorist Iconophobia (and Motor Theories of Imagery)

Where the Gestalt Psychologists, for the most part, ignored the concept of imagery, the Behaviorist movement, which came to dominate American (and, eventually, international) scientific psychology for almost half a century, actively attacked it. To borrow a coinage from Dennett (1978), Behaviorist psychology was thoroughly *iconophobic*. Although the rapid rise of Behaviorism in the United States in the early years of the 20th century certainly had multiple causes, social and institutional as well as intellectual (O'Donnell, 1985), the *imageless thought* controversy, and the questions it raised about introspection as a viable scientific methodology, was certainly prominent amongst the intellectual causes. In the famous "manifesto" by which John B. Watson publicly launched Behaviorism as a self-conscious

movement, the controversy over imageless thoughts is cited as the prime example (indeed, the only really explicit example) of the malaise of psychological methodology, for which Behaviorism would be the cure (Watson, 1913a). In a lengthy footnote to this paper, and in a follow-up article, Watson (1913b) cast doubt on the very existence of mental imagery, a position he was to state more forcefully in later work, where he stigmatized the concept (together with all other remotely mentalistic concepts) as a thoroughly unscientific, "medieval" notion, inextricably bound up with religious belief in an immortal soul, and, as such, barely one step away from "old wives tales" and the superstitions of "savagery" (Watson, 1930). He described personal reports of such things as memory images of one's childhood home as "sheer bunk," nothing more than the sentimental "dramatizing" of verbally mediated memories (i.e. conditioned tendencies to *say* certain things, either out loud or sub-vocally) (Watson, 1928).

Not all American psychologists, even overt Behaviorists, were quite as vehement as Watson in their denunciation of mentality in general, or imagery in particular, but his views certainly resonated with many. The publication of Watson's manifesto (1913a) had, in fact, been preceded by several less radical critiques of introspective methodology from other American psychologists (Danziger, 1980). Particularly relevant here is Knight Dunlap's "The Case Against Introspection" (1912), because Dunlap, who was a junior colleague of Watson in the Johns Hopkins University Psychology Department, seems to have played a crucial if inadvertent role in the formation of Watson's attitude towards imagery, and, thereby, in the crystallization of Behaviorism itself (Cohen, 1979; Thomas, 1989).

During his early days at Johns Hopkins (where he arrived in 1908) Watson, by his own account, believed that "centrally aroused visual sensations [i.e., images] were as clear as those peripherally aroused" (Watson, 1913a), and when Dunlap told Watson of his skepticism concerning what he (Dunlap) called "the old doctrine of images" Watson initially demurred, insisting that he himself made important use of visual imagery, for example in the process of designing experimental apparatus (Dunlap, 1932; cf. Watson, 1936).

However, by this time Watson already seems to have been ambitious to approach human psychology using the methodology that he had already successfully developed for the study of animal behavior (Watson, 1924, 1936). By 1910, and perhaps before, the only real factor preventing Watson from conceiving of the study of behavior as embracing the whole of psychology seems to have been "the problem of the higher thought processes" (Burnham, 1968): Thought was supposed to be carried on primarily in imagery, and imagery was not behavior (see Watson, 1913b). Dunlap's objections to the "old doctrine" that held visual imagery to consist in "centrally aroused visual sensations" seems to have played a crucial role in emboldening Watson to deny the existence of imagery altogether, thus enabling him to present the study of behavior as a fully sufficient methodology for psychology (Watson, 1924; Thomas, 1989).

However, Dunlap never became a Behaviorist himself (Dunlap, 1932), and when his actual views about imagery are examined (Dunlap, 1914) it becomes apparent that he did not intend to deny that people have experiences that are, in a significant sense, quasi-perceptual. Although he described himself as an "iconoclast" (1932), and held that "the image, as a copy or reproduction of sensation . . . does not exist," (Dunlap,1914), Dunlap also asserted that Watson went much too far in rejecting "imagination" as well as

"images" (Dunlap, 1932), and he continued to hold that we are in need of an account of the nature of "ideas". Something, something mental and, indeed, quasi-perceptual, is needed to fill the functional role that images played in the traditional psychology of thinking. It is clear that he (unlike Watson) did not deny the existence of imagery in the sense in which it was defined at the beginning of this article (i.e. quasi-perceptual experience). Dunlap's theory would seem to be best understood as a pioneering (though perhaps, ultimately, unconvincing) attempt to explain both the experience of imagery, and the functional role that it plays in thinking, in a way that avoids postulating the presence of pictures in the head, or inner copies of former sense impressions.

According to Dunlap, *ideas* are actually complexes of muscular sensations, caused by outwardly imperceptible movements, or, at least, tensings, of the muscles, particularly (though not exclusively) the muscles associated with the sense organs themselves, such as those that move the eyes. Particular patterns of muscular response, Dunlap holds, occur during the perception of particular types of objects or events, and may be aroused not only in the course of the actual perception of a relevant object, but also through associative links with the sensations produced by other muscular response patterns appropriate to other sorts of objects or events. These latter patterns may have arisen in actual perception, or may themselves have been aroused associatively in a similar way. Thus, associative trains of thought can be sustained. When the muscular response is aroused associatively, rather than by the actual perceptual presence of the relevant object, we experience the idea, or image, of the object. Visual imagery consists not of copies or echoes of visual sensations, but rather of actual current sensations in the muscles involved in the process of seeing something.

> There is indeed a present content essentially connected with imagination or thought; but this present content is in each case a muscle sensation, or a complex of muscle sensations. We are therefore, in investigating images, dealing not with copies, or pale ghosts, of former sensations but with actual present sensations. (Dunlap, 1914)

These muscle sensations are, explicitly, not to be confused with the impalpable *imageless thoughts* of Würzburg, rather, "This sensation is the true *image*" (Dunlap, 1914, emphasis in original). (For a more extensive account of Dunlap's theory of imagery, and its influence on Watson, see Thomas (1989).)

Dunlap's theory of imagery/ideas was publicly presented only in one brief and rather obscurely published article (Dunlap, 1914) and (apart from its unintended and covert influence on Watson), it seems to have attracted very little interest from his contemporaries. The theory probably owes much to the influence of Hugo Münsterberg, whose "motor theory" of the mind had a considerable vogue amongst American psychologists at the time, but which was soon to be eclipsed by the rise of Behaviorism (Scheerer, 1984). Münsterberg was a German, a former student of Wundt, who had been hired to teach psychology at Harvard when William James moved on, and Dunlap had studied under him before coming to Johns Hopkins (Dunlap, 1932). An earlier "motor" theory of imagery can also be found in the work of the French psychologist Theodule Ribot (1890, 1900) (predating Münsterberg's influence), but the most developed version was surely that of Margaret Floy Washburn, a former student of Titchener. Washburn (unlike Dunlap) is quite open in acknowledging her intellectual debt to Münsterberg (Washburn, 1932), and her book *Movement and Mental Imagery* (Washburn, 1916) goes into considerable, if speculative,

physiological as well as psychological detail. However, by the time this was published Behaviorist iconophobia was already taking firm hold, and Washburn's version of the motor theory of imagery seems to have failed to attract any more adherents than Dunlap's had.

Infamously, during the period of Behaviorist dominance, up until about 1960, mental imagery received minimal attention from scientific psychologists. According to Paivio (1971), the 1920s and 1930s were "the most arid period" for imagery research, but Kessel (1972) reports that even through the 1940s and 1950s a scant five references to imagery are to be found in *Psychological Abstracts*. Admittedly some interest in the psychology of imagery continued outside the United States in this era. In Britain, for example, psychologists such as Pear (1925, 1927), Bartlett (1927, 1932), and, latterly, McKellar (1957) kept an interest in the topic alive. However, this work did not have much contemporaneous impact in the United States, which by the 1930s had already achieved its dominant superpower status in psychology, if not yet in other domains. A general revival of interest in imagery did not get under way in America before the1960s. By that time the Behaviorist consensus was beginning to break down (as can be seen in the work of Mowrer (1960), who tried to patch-up Behaviorist learning theory by introducing the alien concept of imagery into it), and new and striking empirical findings about imagery emerged to play a significant role in the cognitive revolution.

Supplement to Aristotle's Psychology

The Subordinate Psychic Faculties of Imagination and Desire

Imagination

Aristotle sometimes recognizes as a distinct capacity, on par with perception and mind, imagination (*phantasia*) (*De Anima* iii 3, 414b33-415a3). Although he does not discuss it at length, or even characterize it intrinsically in any detailed way, Aristotle does take pains to distinguish it from both perception and mind. In a brief discussion dedicated to imagination (*De Anima* iii 3), Aristotle identifies it as "that in virtue of which an image occurs in us" (*De Anima* iii 3, 428aa1-2), where this is evidently given a broad range of application, including the activities involved in thoughts, dreams, and memories. Aristotle is, however, mainly concerned to distinguish imagination from perception and mind. He distinguishes it from perception on a host of grounds, including: (i) imagination produces images when there is no perception, as in dreams; (ii) imagination is lacking in some lower animals, even though they have perception, which shows that imagination and perception are not even co-extensive; and (iii) perception is, Aristotle claims, always true, whereas imagination can be false, false even in fantastic ways (*De Anima* iii 3, 428a5-16). He also denies that imagination can be identified with mind or belief, or any combination of belief and perception (*De Anima* iii 3, 428a16-b10), even though it comes about through sense perception (*De Anima* iii 3, 429a1-2; *De Insomniis* 1, 459a17). The suggestion, then, is that imagination is a faculty in humans and most other animals which produces, stores, and recalls the images used in a variety of cognitive activities, including those which motivate and guide action (*De Anima* iii 3, 429a4-7, *De Memoria* 1, 450a22-25).

Because he tends to treat imagination pictographically (*De Anima* iii 3, 429a2-4; cf. *De Sensu* 1, 437a3-17; 3, 439b6), Aristotle seems to regard the images used in cognitive processes as representations best thought of on the model of copies or likenesses of external objects. This much he holds in common with many other empirically oriented cognitive psychologists. Typically he will suggest, in this vein, that thought requires images, both genetically and concurrently, so that "whenever one contemplates, one necessarily at the same time contemplates in images" (*De Anima* iii 8, 432a8-9, 431a16-17; *De Memoria* 1, 449b31-450a1). His suggestions in this direction may seem unfortunate, since for a broad range of thoughts, images, construed naturally and narrowly as pictorial representations, seem unnecessary or even plainly irrelevant. (It is hard to fathom, e.g., what image corresponds to the thought that gerunds make for ungainly syntax--still less is it clear what grounds could compel one to agree that some image or other must accompany it). Perhaps, though, his remarks should be tempered by the recognition that Aristotle accepts the existence of a thinking god whose activity is exhausted by thinking, but whose thinking is not plausibly regarded as imagistic (*Metaphysics* xii 7,1072b26-30). If that is so, Aristotle

could not accept the thesis that for any episode of thought *t*, necessarily *t* is or is directed upon a pictorial image. Still, Aristotle clearly expects images, so construed, to play a central or even indispensable role in human cognition.

Return to Aristotle's Psychology

First posted: January 11, 2000

Aristotle's Psychology

Aristotle (384-322 BC) was born in what was to become Macedon in northern Greece, but spent most of his adult life in Athens. His life in Athens divides into two periods, first as a member of Plato's Academy (367-347) and later as director of his own school, the Lyceum (334-323). The intervening years were spent mainly in Assos and Lesbos, and briefly back in Macedon. His years away from Athens were predominantly taken up with biological research and writing. Judging on the basis of their content, Aristotle's most important psychological writings probably belong to his second residence in Athens, and so to his most mature period. His principal work in psychology, *De Anima*, reflects in different ways his pervasive interest in biological taxonomy and his most sophisticated physical and metaphysical theory.

Because of the long tradition of exposition which has developed around Aristotle's *De Anima*, the interpretation of even its most central theses is sometimes disputed. Moreover, because of its evident affinities with some prominent approaches in contemporary philosophy of mind, Aristotle's psychology has received renewed interest and has incited intense interpretative dispute in recent decades. Consequently, this entry proceeds on two levels. The main article recounts the principal and distinctive claims of Aristotle's psychology, avoiding so far as possible exegetical controversy and critical commentary. At the end of appropriate sections of the main article, readers are invited to explore problematic or advanced features of Aristotle's theories by moving to a lower level.

Aristotle's Psychological Writings

Aristotle investigates psychological phenomena primarily in *De Anima* and a loosely related collection of short works called the *Parva Naturalia*, whose most noteworthy pieces are *De Sensu* and *De Memoria*. He also touches upon psychological topics, often only incidentally, in his ethical, political, and metaphysical treatises, as well as in his scientific writings, especially *De Motu Animalium*. The works in the *Parva Naturalia* are, in comparison with *De Anima*, empirically oriented, investigating, as Aristotle says, "the phenomena common to soul and body" (*De Sensu* 1, 436a6-8). This contrasts with *De Anima*, which introduces as a question for consideration "whether all affections are common to what has the soul or whether there is some affection peculiar to the soul itself" (*De Anima* i 1, 402a3-5). That is, in *De Anima* Aristotle wants to know whether all psychological states are also material states of the body. "This," he remarks, "it is necessary to grasp, but not easy" (*De Anima* i 1, 402a5). In this way, *De Anima* proceeds at a higher level of abstraction than the *Parva Naturalia*. It is generally more theoretical, more self-conscious about method, and more alert to general philosophical questions about perception, thinking, and soul-body relations.

In both *De Anima* and the *Parva Naturalia*, Aristotle assumes something which may strike some of his modern readers as odd. He takes psychology to be the branch of science which investigates the soul and its properties, but he thinks of the soul as a general principle of life, with the result that psychology studies all living beings, and not merely those he regards as having minds, human beings. So, in *De Anima*, he takes it as his task to provide an account of the life activities of plants and animals, along side those of humans (*De Anima* ii 11, 423a20-6, cf. ii 1, 412a13; cf. *De Generatione Animalium* ii 3, 736b13; *De Partibus Animalium* iv 5, 681a12). In comparison with the modern discipline of Psychology, then, Aristotle's psychology is broad in scope. He even devotes attention to the question of the nature of life itself, a subject which falls outside the purview of psychology in most contemporary contexts. On Aristotle's approach, psychology studies the soul (*psuchê* in Greek, or *anima* in Latin); so it naturally investigates all ensouled or animate beings.

Hylomorphism in General

In *De Anima*, Aristotle makes extensive use of technical terminology introduced and explained elsewhere in his writings. He claims, for example, using vocabulary derived from his physical and metaphysical theories, that the soul is a "first actuality of a natural organic body" (*De Anima* ii 1, 412b5-6), that it is a "substance as form of a natural body which has life in potentiality" (*De Anima* ii 1, 412a20-1) and, similarly, that it "is a first actuality of a natural body which has life in potentiality" (*De Anima* ii 1, 412a27-8), all claims which apply to plants, animals and humans alike.

In characterizing the soul and body in these ways, Aristotle applies concepts drawn from his broader *hylomorphism*, a conceptual framework which underlies virtually all of his mature theorizing. It is accordingly necessary to begin with a brief overview of that framework. Thereafter it will be possible to recount Aristotle's general approach to soul-body relations, and then, finally, to consider his analyses of

the individual faculties of soul.

‘Hylomorphism’ is simply a compound word composed of the Greek terms for matter (*hulê*) and form or shape (*morphê*); thus one could equally describe Aristotle's view of soul and body as an instance of his "matter-formism". That is, when he introduces the soul as the *form* of the body, which in turn is said to be the *matter* of the soul, Aristotle treats soul-body relations as a special case of a more general relationship which obtains between the components of all generated compounds, natural or artifactual.

The notions of form and matter are themselves, however, developed within the context of a general theory of causation and explanation which appears in one guise or another in all of Aristotle's mature works. According to this theory, when we wish to explain what there is to know, for example, about a bronze statue, a complete account necessarily alludes to at least the following four factors: the statue's matter, its form or structure, the agent responsible for that matter's manifesting its form or structure, and the purpose for which the matter was made to realize that form or structure. These four factors he terms the four causes (*aitiai*):

The *material cause*: that from which something is generated and out of which it is made, e.g. the bronze of a statue.
The *formal cause*: the structure which the matter realizes and in terms of which the matter comes to be something determinate, e.g. the Hermes shape in virtue of which this quantity of bronze is said to be a statue of Hermes.
The *efficient cause*: the agent responsible for a quantity of matter's coming to be informed, e.g. the sculptor who shaped the quantity of bronze into its current Hermes shape.
The *final cause*: the purpose or goal of the compound of form and matter, e.g. the statue was created for the purpose of honoring Hermes.

For a broad range of cases, Aristotle implicitly makes twin claims about these four causes: (i) a complete explanation requires reference to all four; and (ii) once such reference is made, no further explanation is required. Thus, when appropriate, appeal to the four causes is both necessary and sufficient for complete and adequate explanation. Although not all things which admit of explanation have all four causes, e.g. geometrical figures are not efficiently caused, even a brief overview of his psychological writings reveals that Aristotle regards all four causes as in play in the explanation of living beings. A monkey, for example, has matter, its body; form, its soul; an efficient cause, its parent; and a final cause, its function. Moreover, he holds that the form is the *actuality* of the body which is its matter: an indeterminate lump of bronze becomes a statue only when it realizes some particular statue-shape. So, Aristotle suggests, that matter is *potentially* some F until it acquires an actualizing form, when it becomes actually F. Given his overarching explanatory schema, it is hardly surprising that Aristotle should advance a hylomorphic account of soul and body; this is, for him, standard explanatory procedure.

Still, it is noteworthy that this four-causal framework of explanation is developed initially in response to

some puzzles about change and generation. Aristotle argues with some justification that all change and generation require the existence of something complex: when a statue comes to be from a lump of bronze, there is some continuing subject, the bronze, and something it comes to acquire, its new form. Thus the statue is, and must be, a certain kind of compound, one of form and matter. Without this type of complexity, generation would be impossible; since generation in fact occurs, form and matter must be genuine features of generated compounds. Similarly, but less obviously, qualitative change requires much the same apparatus: when a statue is painted, there is some continuing subject, the statue, and a new feature acquired, its new color. Here too there is complexity, and complexity which is readily articulated in terms of form and matter, but now of form which is evidently inessential to the continued existence of the entity whose form it is. The statue continues to exist, but receives a form which is accidental to it; it might lose that form without going out of existence. By contrast, should the statue lose its essential form, as would happen for example if the bronze which constitutes it were melted, divided, and recast as twelve dozen letter openers, it would cease to exist altogether.

For the purposes of understanding Aristotle's psychology, the origin of Aristotle's hylomorphism is significant for two reasons. First, from its inception, Aristotle's hylomorphism exploits two distinct but related notions of form, one of which is essential to the compound whose form it is, and the other of which is accidental to its subject. In advancing his view of the soul and its capacities, Aristotle employs both of these notions: the soul is an essential form, whereas perception involves the acquisition of accidental forms. Second, because Aristotle's hylomorphism was initially developed to handle puzzles of change and generation, its deployment in philosophical psychology is sometimes strained, insofar as Aristotle is not immediately willing to treat every instance of perception and thought as a straightforward instance of change in some continuing subject.

Hylomorphic Soul-Body Relations

In applying his general hylomorphism to soul-body relations, Aristotle contends that the following general analogy obtains:

soul : body : : form : matter : : Hermes-shape : bronze

If the soul bears the same relation to the body which the shape of a statue bears to its material basis, then we should expect some general features to be common to both; and we should be able to draw some immediate consequences regarding the relationship between soul and body. To begin, some questions about the unity of soul and body, an issue of concern to substance dualists and materialists alike, receive a ready response. Materialists hold that all mental states are also physical states; substance dualists deny this, because they hold that the soul is a subject of mental states which can exist alone, when separated from the body. In a certain way, the questions which give rise to this dispute simply fall by the wayside. If we do not think there is an interesting or important question concerning whether the Hermes-shape and its material basis are one, we should not suppose there is a special or pressing question about whether the soul and body are one. So Aristotle contends: "It is not necessary to ask whether soul and body are one,

just as it is not necessary to ask whether the wax and its shape are one, nor generally whether the matter of each thing and that of which it is the matter are one. For even if one and being are spoken of in several ways, what is properly so spoken of is the actuality" (*De Anima* ii 1, 412b6-9). Aristotle does not here eschew questions concerning the unity of soul and body as meaningless; rather, he seems, in a deflationary vein, to suggest that they are readily answered or somehow unimportant. If we do not spend time worrying about whether the wax of a candle and its shape are one, then we should not exercise ourselves over the question of whether the soul and body are one. The effect, then, is to fit soul-body relations into a larger pattern of explanation, hylomorphism, in terms of which questions of unity do not normally arise.

It should be emphasized, however, that Aristotle does not here decide the question by insisting that the soul and body are identical, or even that they are one in some weaker sense; indeed, this is something he evidently denies (*De Anima* ii 1, 412a17; ii 2, 414a1-20). Instead, just as one might well insist that the wax of a candle and its shape are distinct, on the grounds that the wax could easily exist when the particular shape is no more, or, less obviously, that the particular shape could survive the replenishment of its material basis, so one might equally deny that the soul and body are identical. In a fairly direct way, though, the question of whether soul and body are one loses its force when it is allowed that it contains no implications beyond those we establish for any other hylomorphic compound, including houses and other ordinary artifacts.

One way of appreciating this is to consider a second general moral Aristotle derives from hylomorphism. This concerns the question of the separability of the soul from the body, a possibility embraced by substance dualists from the time of Plato onward. Aristotle's hylomorphism commends the following attitude: if we do not think that the Hermes-shape persists after the bronze is melted and recast, we should not think that the soul survives the demise of the body. So, Aristotle claims, "It is not unclear that the soul-or certain parts of it, if it naturally has parts-is not separable from the body" (*De Anima* ii 1, 413a3-5). So, unless we are prepared to treat forms in general as capable of existing without their material bases, we should not be inclined to treat souls as exceptional cases. Hylomorphism, by itself, gives us no reason to treat souls as separable from bodies, even if we think of them as distinct from their material bases. At the same time, Aristotle does not appear to think that his hylomorphism somehow refutes all possible forms of dualism. For he appends to his denial of the soul's separability the observation that some parts of the soul may in the end be separable after all, since they are not the actualities of any part of the body (*De Anima* ii 1, 413a6-7). Aristotle here prefigures his complex attitude toward mind (*nous*), a faculty he repeatedly describes as exceptional among capacities of the soul.

Still, in general, the soul is the form of the body in much the same way the form of a house structures the bricks and mortar from which it is built. When the bricks and mortar realize a certain shape, they manifest the function definitive of houses, namely that of providing shelter. Thus, the presence of the form makes those bricks and that mortar a house, as opposed, e.g., to a wall or an oven. As we have seen, Aristotle will say that the bricks and mortar, as matter, are potentially a house, until they realize the form appropriate to houses, in which case the form and matter together make an actual house. So, in Aristotle's terms, the form is the actuality of the house, since its presence explains why this particular quantity of

matter comes to be a house as opposed to some other kind of artifact.

In the same way, then, the presence of the soul explains why this matter is the matter of a human being, as opposed to some other kind of thing. Now, this way of looking at soul-body relations as a special case of form-matter relations treats reference to the soul as an integral part of any complete explanation of a living being, of any kind. To this degree, Aristotle thinks that Plato and other dualists are right to stress the importance of the soul in explanations of living beings. At the same time, he sees their commitment to the separability of the soul from the body as unmotivated by a mere appeal to formal causation: he will allow that the soul is distinct from the body, and is indeed the actuality of the body, but he sees that these concessions by themselves provide no grounds for supposing that the soul can exist without the body. His hylomorphism, then, embraces neither reductive materialism nor Platonic dualism. Instead, it seeks to steer a middle course between these alternatives by pointing out, implicitly, and rightly, that these are not exhaustive options.

Psychic Faculties

Although willing to provide a common account of the soul in these general terms, Aristotle devotes most of his energy in *De Anima* to detailed investigations of the soul's individual capacities, which include nutrition, perception, and mind, with perception receiving the lion's share of attention. The broadest is nutrition, which is shared by all natural living organisms; animals have perception in addition; and among natural organisms humans alone have mind. Aristotle maintains that various kinds of souls, nutritive, perceptual, and intellectual, form a kind of hierarchy. Any creature with reason will also have perception; any creature with perception will also have the ability to take on nutrition and to reproduce; but the converse does not hold. Thus, plants show up with only the nutritive soul, animals have both perceptual and nutritive faculties, and humans have all three. The reasons why this should be so are broadly teleological. In brief, every living creature as such grows, reaches maturity, and declines. Without a nutritive capacity, these activities would be impossible (*De Anima* iii 12, 434a22-434b18; cf. *De Partibus Animalium* iv 10, 687a24-690a10; *Metaphysics*xii 10, 1075a16-25). So, Aristotle concludes, psychology must investigate not only perceiving and thinking, but also nutrition.

There is some dispute about which of the psychic abilities mentioned by Aristotle in *De Anima* qualify as full-fledged or autonomous faculties. He evidently accepts the three already mentioned as centrally important. Indeed, he is willing to demarcate a hierarchy of life in terms of them. Even so, he also discusses two other capacities, imagination (*De Anima* iii 3) and desire (*De Anima* iii 9 and 10), and appeals to them both in his account of thinking and his philosophy of action. He does little, however, to characterize them in any intrinsic way; he evidently regards them as subordinate faculties, integrated in various ways with the faculties of nutrition, perception, and thought. Each of them raises interesting questions about how Aristotle views the various capacities of soul as integrating into unified forms. His main deployment of a hylomorphic analysis, however, extends only to the individual capacities of nutrition, perception, and mind.

Nutrition

When turning to these individual faculties of the soul, Aristotle considers nutrition first, for two related reasons. The first is straightforward: psychology considers all animate entities, and the nutritive soul belongs to all naturally living things, since it is "the first and most common capacity of soul, in virtue of which life belongs to all living things" (*De Anima* ii 4, 415a24-25). The second is slightly more complex, being at root teleological. Given that the higher forms of soul presuppose nutrition, its explication is prior to them in the order of Aristotle's exposition.

Aristotle approaches his account of the nutritive soul by relying on a methodological precept which informs much of his psychological theorizing, namely that a capacity is individuated by its objects, so that, e.g., perception is distinguished from mind by being arrayed toward sensible qualities rather than intelligible forms (*De Anima* ii 4, 415a20-21). This induces him to offer what may sound initially like a pedestrian observation, that in nutrition there are three components, "that which is nourished, that by which it is nourished, and what nourishes (i.e. that which engages in nutrition)." This, however, Aristotle unpacks by maintaining that "what nourishes is the primary soul; what is nourished is the body which has this soul; and that by which it is nourished is nourishment (i.e. food)" (*De Anima* ii 4, 416b20-23). The interest of this suggestion lies in the implication that all and only living systems can be nourished, a consequence Aristotle makes more explicit by claiming that "nothing is nourished which does not have a share in life" (*De Anima* ii 4. 415b27-28) and that "since nothing is nourished which does not partake of life, what is nourished will be the ensouled body insofar as it is ensouled, with the result that nourishment (i.e. food) is related to the ensouled, and not coincidentally" (*De Anima* ii 4, 416b9-11). Here Aristotle means that food, as food, is definitionally related to life. Whatever is food is already such as to be necessarily related to living beings.

The significance of this observation resides in the thought that any adequate account of nutrition will make ineliminable reference to life as such. This in turn entails that it will not be possible to *define* life as the capacity for taking on nutrition. For then we would have a vicious circularity: a living system is the sort of thing which can take on nutrition, while nutrition is whatever stuff is such as to sustain a living system. So, if living systems cannot be reductively defined in some other way, it will follow that no reductive account of life will be forthcoming. Consequently, Aristotle's discussion of nutrition provides some reason for thinking that he will resist any attempt to define life in terms which do not themselves implicitly appeal to life itself. That is, he will resist any reductive account of life.

This also seems to be the purport of Aristotle's rejection of the simple mechanistic accounts of growth which he considers when discussing the nutritive soul (*De Anima* ii 4, 415b27-416a20; cf. *De Generatione et Corruptione* i 5). Aristotle objects to those who want to account for growth merely in terms of the natural tendencies of material elements. For growth is a *constrained* pattern of development, the source of which Aristotle ascribes to the soul. He takes it as manifest that growth in organisms proceeds along structured paths, in end-directed ways. These structures in turn manifest capacities whose explication cannot be given in crude materialistic terms; for materialistic terms, as Aristotle understands them, fail to account for the fact that mature members of species cease growing, having realized the

structures characteristic of their kind. Fire, for example, by contrast "grows" haphazardly, without directionality, moving toward the combustible without end, until hindered by external impediments or lack of fuel.

Now, the forms of materialist explanations Aristotle considers are primitive. One critical question about his treatment of these explanations concerns whether he is right to suggest that facts about constrained patterns of development are incompatible with more explanatorily advanced forms of materialism, and, if so, whether those forms of materialism will be reductive in the sense that they will avoid all implicit or explicit reference to life. So far, there is little reason to think that Aristotle has been proven wrong; that is, there is at present no reductive account of life which enjoys universal or even broad support.

In any case, Aristotle's discussion of nutrition is characteristic of his general approach to the soul's faculties. His discussions often proceed on two levels. On the one hand, he simply seeks to provide an account of the relevant phenomena. At the same time, his interests in definition are conditioned by a host of broader methodological and metaphysical concerns. Consequently, he attempts to capture the nature of the individual faculties while at the same time investigating whether reductive accounts of them are plausible. In this way, at least, Aristotle's investigations reflect sensitivity to a host of questions in definitional methodology, including most notably questions about the plausibility of reductive approaches to life's most characteristic features. These same interests are apparent in his discussions of perception and mind.

Perception

Aristotle devotes a great deal of attention to perception, discussing both the general faculty and the individual senses. In both cases, his discussions are cast in hylomorphic terms. Perception is the capacity of the soul which distinguishes animals from plants; indeed, having a perceptive faculty is definitive of being an animal (*De Sensu* 1, 436b10-12). In broad terms at least, animals must have perception if they are to live. So, Aristotle supposes, there are defensible teleological grounds for treating animals as essentially capable of perceiving (*De Anima* ii 3, 414b6-9, 434a30-b4; *De Sensu* 1, 436b16-17). If an animal is to grow to maturity and propagate, it must be able to take in nourishment and to navigate its way through the world. Perception serves these ends.

This much, however, does not explain how perception occurs. Aristotle claims that perception is best understood on the model of hylomorphic change generally: just as a house changes from blue to white when acted upon by the agency of a painter applying paint, so "perception comes about with <an organ's> being changed and affected. . .for it seems to be a kind of alteration" (*De Anima* ii 5, 416b33-34). So, in line with his general account of alteration, Aristotle treats perception as a case of interaction between two suitable agents: objects capable of acting and capacities capable of being affected. That the agents and patients must both be *suitable* is important, since we need to distinguish between two ways, e.g., an odor might affect something. By being placed in its vicinity, a clove of garlic might affect a block of tofu. The tofu might come to take on the odor of the garlic. But we would not want to say that the tofu perceives the garlic. By contrast, when an animal is affected by the same clove, it perceives the odor.

Since the garlic is the same in both cases, the difference in these cases must reside in the character of the object affected: when animals receive forms, perception results.

In both kinds of alterations, Aristotle is happy to speak of an affected thing as receiving the form of the agent which affects it and of the change consisting in the affected thing's "becoming like" the agent (*De Anima* ii 5, 418a3-6; ii 12, 424a17-21). So, there is in both cases, a hylomorphic model of alteration involving "enforming", that is, a model according to which change is explained by the acquisition of a form by something capable of receiving it. Consequently, whatever is changed in a given way is necessarily such that it is capable of being changed in that way. This is not the mere triviality that whatever becomes actually F must already be possibly F. Instead, it is the recognition that specific forms of change require suitable capacities in the changing subjects, and that, consequently, analyses of specific forms of change will necessarily involve consideration of those capacities. No marshmallow can receive the form of an actual automobile; and only entities capable of perceiving can receive the perceptible forms of objects. This is Aristotle's meaning when he claims: "the perceptive faculty is in potentiality such as the object of perception already is in actuality" and that when something is affected by an object of perception, "it is made like it and is such as that thing is" (*De Anima* ii 5, 418a3-6).

This hylomorphic restriction on the suitability of subjects of change has the effect of limiting cases of actual perception to those instances of form-reception which involve living beings endowed with the appropriate faculties. It does not, however, explain just what those faculties are, nor even how they are "made like" their objects of perception. Minimally, though, Aristotle claims that for some subject S and some sense object O:

S perceives O if and only if: (i) S has the capacity requisite for receiving O's sensible form; (ii) O acts upon that capacity by enforming it; and, as a result, (iii) S's relevant capacity becomes isomorphic with that form.

Each of these clauses requires unpacking. The plausibility of Aristotle's theory turns on their eventual explications. The first clause (i) is intended to distinguish the active capacities of animals from the merely passive capacities of lifeless material bodies, including the media through which sensible forms travel. (Just as we do not want to say that the tofu in the refrigerator perceives the garlic next to it, we do not want to say that air perceives the color blue when affected by the color of a car.) But it does not yet specify what is required for having the requisite active capacities. Also difficult is the notion of isomorphism appealed to in (iii). As stated, (iii) invites, and has received, scrutiny. Interpretations range from treating the form of isomorphism as direct and literal, so that, e,g., the eyes become speckled when viewing a robin's egg, to attenuated, where the isomorphism is more akin to that enjoyed between a house and its blue-print. Here especially the plausibility of Aristotle's hylomorphic analysis of perception hangs in the balance.

Mind

Aristotle describes mind (*nous*) as "the part of the soul by which it knows and understands" (*De Anima* iii 4, 429a9-10; cf. iii 3, 428a5; iii 9, 432b26; iii 12, 434b3), thus characterizing it in broadly functional terms. It is plain that humans can know and understand things; indeed, Aristotle supposes that it is our very nature to desire knowledge and understanding (*Metaphysics* i 1, 980a21; *De Anima* ii 3, 414b18; iii 3, 429a6-8). In this way, just as the having of sensory faculties is essential to being an animal, so the having of a mind is essential to being a human. Investigating this capacity of soul thus has a special significance for Aristotle: in investigating mind, he is investigating what makes humans human.

His primary investigation of mind occurs in two chapters of *De Anima*, both of which are richly suggestive, but neither of which admits of easy or uncontroversial exposition. In them, *De Anima* iii 4 and 5, Aristotle approaches the nature of thinking by once again deploying a hylomorphic analysis, given in terms of form reception. Just as perception involves the reception of a sensible form by a suitably qualified sensory faculty, so thinking involves the reception of an intelligible form by a suitably qualified intellectual faculty (*De Anima* iii 4, 429a13-18). According to this model, thinking consists in a mind's becoming enformed by some object of thought, so that actual thinking occurs whenever some suitably prepared mind is "made like" its object by being affected by it.

This hylomorphic analysis of thinking is evidently a simple extension of the general model of hylomorphic change exploited by Aristotle in a host of similar contexts. Accordingly, Aristotle's initial account of thinking will directly parallel his analysis of perception (*De Anima* iii 4, 429a13-18). That is, at least in schematic outline, Aristotle will offer the following approach, for any given thinker S and an arbitrary object of thought O:

S thinks O if and only if: (i) S has the capacity requisite for receiving O's intelligible form; (ii) O acts upon that capacity by enforming it; and, as a result, (iii) S's relevant capacity becomes isomorphic with that form.

Unsurprisingly, the same questions which arose in the case of perception also arise here. Most immediately, to understand Aristotle's approach to thinking, it is necessary to determine what it means to say that a thinker's mind and its object become isomorphic.

Here, at least, Aristotle points out what is obvious, that when a thinker's soul is made like its cognitive object, it does not become one with some hylomorphic compound, but with its form: "for it is not the stone which is in the soul, but its form" (*De Anima* iii 8, 431b29-432a1; cf. iii 4, 429a27). The suggestion is, then, that when S comes to think of a stone, as opposed to merely perceiving some particular stone, S has a faculty which is such that it can become one in form with that stone. Aristotle sometimes infers from this sort of consideration that thought is of universals, whereas perception is of particulars (*De Anima* ii 5, 417b23, *Posterior Analytics* i 31, 87b37-88a7), though he elsewhere will allow that we also have knowledge of individuals (*De Anima* ii 5, 417a29; *Metaphysics* xiii 10, 1087a20). These passages are not contradictory, since Aristotle may simply be emphasizing that thought tends to proceed at a higher level of generality than perception, because of its trading in comparatively abstract structural features of its objects. A person can think of what it is to be a stone, but cannot, in any direct and literal

sense of the term, perceive this.

However that may be, Aristotle's conception of thinking implicates him in supposing that thought involves grasping the structural features of the objects of thought. To take an initially favorable case, when thinking *that tree frogs are oviparous*, S will be in a psychic state whose internal structural states are, among other things, one in form with tree frogs. Since S's soul does not become a tree frog when thinking of tree frogs, this form of isomorphism cannot be mere instantiation of the form *being a tree frog*. Rather, S's mind will evidently be one in form with the tree frog, to revert to our earlier analogy, in something like the way a blueprint and the house of which it is the blueprint are one in form. There must be a determinate and expressible structural isomorphism, even though one could not say that the blueprint realizes the form of the house: houses are, after all, necessarily three-dimensional.

For Aristotle, it is not a contingent state of affairs that S's mind does not realize the form being a tree frog in the way that tree frogs themselves do. On the contrary, the mind *cannot* realize a broad range of forms: the mind is, according to Aristotle, not "mixed with the body", insofar as it, unlike the perceptual faculty, lacks a bodily organ (*De Anima* iii 4, 429a24-7). As such, it would not be possible for the mind to realize the form of a house in the way bricks and mortar instantiate such a form: houses provide shelter, something a mind, so understood, cannot do. Consequently, when claiming that minds become isomorphic with their objects, Aristotle must understand the way in which minds become enformed as somehow attenuated or non-literal. Perhaps, though, this should be plain enough. If a mind thinks something by being made like it, then the way it is likened to what it thinks must be somehow representational. Consequently, Aristotle is reasonably understood as holding that S thinks some object of thought O whenever S's mind is made like that object by representing salient structural features of O by being directly isomorphic with them, without, that is, by simply realizing the form of O in the way O does.

This approach to the nature of thinking has some promising features. Both in its own terms, and in virtue of its fitting into a broader pattern of explanation, Aristotle's hylomorphic analysis merits serious consideration. At the same time, one of its virtues may appear also as a vice. We noted in discussing Aristotle's hylomorphic analysis of change generally that his account requires the existence of suitably disposed subjects of change. Only surfaces can be affected so as to be changed in color. An action, such as Socrates' becoming unnerved by a glance of Alcibiades, cannot be made white; it is simply not the appropriate sort of subject. So, hylomorphic change requires at least the following two components: (i) something pre-existing to be the patient of the change, and (ii) that thing's being categorially suited to be changed in the way specified.

Already at the first stage, however, Aristotle's application of this hylomorphic analysis of change to thinking may seem an over-extension. For he maintains directly that mind is "none of the things existing in actuality before thinking" (*De Anima* iii 4, 429a24). His reasons for maintaining this thesis are complex, but derive ultimately from the forms of plasticity Aristotle believes the mind must manifest if it is to be capable of thinking all things (*De Anima* iii 4, 429a18). Now, if the mind is indeed nothing in actuality before thinking, it is hard to understand how the hylomorphic analysis of change and affection could be brought to bear in this arena. If some dough is made cookie-shaped, it is actually dough before

being so enformed; even the sense organs, when made like their objects, are actually existing organs before being affected by the objects of perception. So, given a conception of mind as not existing in actuality before thinking, it is hard to appreciate how thinking lends itself to an analysis in terms of any recognizable hylomorphic approach to change.

How great a problem this will be depends in part upon how entrenched Aristotle's commitment to mind's being nothing in actuality before thinking turns out to be. It equally turns on how adaptable Aristotle's hylomorphic account of change proves. On this latter point, Aristotle notes that according to that account, there are various different types of change and alteration, illustrated by the difference between a brown fence's being painted white and a builder's taking up his tools and beginning to build. In the first case, there is a destruction and a loss, of the fence's original color; in the second case, nothing is destroyed, but rather that which is already dispositionally F becomes occurently F by engaging in some F-ish activity. A builder is as such already able to build. When he begins building he becomes fully and actually a builder for the duration of his working. In this way, he loses nothing, but instead realizes an already established potential.

This second type of change, which Aristotle maintains is the appropriate model for many psychic activities, is either "not an instance of alteration. . .or is a different kind of alteration," where one "should not speak of being affected, unless <one allows that> there are two kinds of alteration" (*De Anima* ii 5, 417b6-16). Perhaps Aristotle's position will then be that the mind, at least insofar as its cognitive capacities for thought are concerned, is simply such as to be enformed by any of an infinite range of objects of thought. This would involve its being nothing determinate in itself; and far from being anomalous for Aristotle, the mind would be in the cognitive realm precisely what the most basic stuff, if there is a most basic stuff, would be in the material realm. Both would manifest unconstrained plasticity; and so each would be characterized essentially in terms of their range of potentialities.

That said, it should be noticed that when it is detached from the idiosyncratic thesis that the mind is nothing in actuality before thinking, Aristotle's hylomorphic analysis of thought retains whatever plausibility it may have independently. For the suggestion that thinking is to be understood at least partially in terms of isomorphisms between our representational capacities and the objects of our cognition has had, for good reason, a durable appeal. To the degree that hylomorphism is generally defensible, then, its application in this domain provides a theoretically rich framework for investigating the nature of thought.

The Philosophy of Neuroscience

Over the past three decades, philosophy of science has grown increasingly "local." Concerns have switched from general features of scientific practice to concepts, issues, and puzzles specific to particular disciplines. Philosophy of neuroscience is a natural result. This emerging area was also spurred by remarkable recent growth in the neurosciences. Cognitive and computational neuroscience continues to encroach upon issues traditionally addressed within the humanities, including the nature of consciousness, action, knowledge, and normativity. Empirical discoveries about brain structure and function suggest ways that "naturalistic" programs might develop in detail, beyond the abstract philosophical considerations in their favor.

The literature distinguishes "philosophy of neuroscience" and "neurophilosophy." The former concerns foundational issues within the neurosciences. The latter concerns application of neuroscientific concepts to traditional philosophical questions. Exploring various concepts of representation employed in neuroscientific theories is an example of the former. Examining implications of neurological syndromes for the concept of a unified self is an example of the latter. In this entry, we will assume this distinction and discuss examples of both.

Before and After *Neurophilosophy*

Contrary to some opinion, actual neuroscientific discoveries have exerted little influence on the details of materialist philosophies of mind. The "neuroscientific milieu" of the past four decades has made it harder

for philosophers to adopt dualism. But even the "type-type" or "central state" identity theories that rose to brief prominence in the late 1950s (Place, 1956; Smart, 1959) drew upon few actual details of the emerging neurosciences. Recall the favorite early example of a psychoneural identity claim: pain is identical to C-fiber firing. The "C fibers" turned out to be related to only a single aspect of pain transmission (Hardcastle, 1997). Early identity theorists did not emphasize psychoneural identity hypotheses, admitting that their "neuro" terms were placeholders for concepts from future neuroscience. Their arguments and motivations were philosophical, even if the ultimate justification of the program was held to be empirical.

The apology for this lacuna by early identity theorists was that neuroscience at that time was too nascent to provide any plausible identities. But potential identities were afoot. David Hubel and Torsten Wiesel's (1962) electrophysiological demonstrations of the receptive field properties of visual neurons had been reported with great fanfare. Using their techniques, neurophysiologists began discovering neurons throughout visual cortex responsive to increasingly abstract features of visual stimuli: from edges to motion direction to colors to properties of faces and hands. More notably, Donald Hebb had published *The Organization of Behavior* (1949) a decade earlier. Therein he offered detailed explanations of psychological phenomena in terms of known neural mechanisms and anatomical circuits. His psychological explananda included features of perception, learning, memory, and even emotional disorders. He offered these explanations as potential identities. (See the Introduction to his 1949). One philosopher who did take note of some available neuroscientific detail was Barbara Von Eckardt-Klein (1975). She discussed the identity theory with respect to sensations of touch and pressure, and incorporated then-current hypotheses about neural coding of sensation modality, intensity, duration, and location as theorized by Mountcastle, Libet, and Jasper. Yet she was a glaring exception. By and large, available neuroscience at the time was ignored by both philosophical friends and foes of early identity theories.

Philosophical indifference to neuroscientific detail became "principled" with the rise and prominence of functionalism in the 1970s. The functionalists' favorite argument was based on multiple realizability: a given mental state or event can be realized in a wide variety of physical types (Putnam, 1967; Fodor, 1974). So a detailed understanding of one type of realizing physical system (e.g., brains) will not shed light on the fundamental nature of mind. A psychological state-type is autonomous from any single type of its possible realizing physical mechanisms. (See the entry on "Multiple Realizability" in this Encyclopedia, linked below.) Instead of neuroscience, scientifically-minded philosophers influenced by functionalism sought evidence and inspiration from cognitive psychology and "program-writing" artificial intelligence. These disciplines abstract away from underlying physical mechanisms and emphasize the "information-bearing" properties and capacities of representations (Haugeland, 1985). At this same time neuroscience was delving directly into cognition, especially learning and memory. For example, Eric Kandel (1976) proposed presynaptic mechanisms governing transmitter release rate as a cell-biological explanation of simple forms of associative learning. With Robert Hawkins (1984) he demonstrated how cognitivist aspects of associative learning (e.g., blocking, second-order conditioning, overshadowing) could be explained cell-biologically by sequences and combinations of these basic forms implemented in higher neural anatomies. Working on the post-synaptic side, neuroscientists began unraveling the cellular mechanisms of long term potentiation (LTP) (Bliss and Lomo, 1973). Physiological psychologists quickly

noted its explanatory potential for various forms of learning and memory.[1] Yet few "materialist" philosophers paid any attention. Why should they? Most were convinced functionalists. They believed that the "engineering level" details might be important to the clinician, but were irrelevant to the theorist of mind.

A major turning point in philosophers' interest in neuroscience came with the publication of Patricia Churchland's *Neurophilosophy* (1986). The Churchlands (Pat and husband Paul) were already notorious for advocating eliminative materialism (see the next section). In her (1986) book, Churchland distilled eliminativist arguments of the past decade, unified the pieces of the philosophy of science underlying them, and sandwiched the philosophy between a five-chapter introduction to neuroscience and a 70-page chapter on three then-current theories of brain function. She was unapologetic about her intent. She was introducing philosophy of science to neuroscientists and neuroscience to philosophers. Nothing could be more obvious, she insisted, than the relevance of empirical facts about how the brain works to concerns in the philosophy of mind. Her term for this interdisciplinary method was "co-evolution" (borrowed from biology). This method seeks resources and ideas from anywhere on the theory hierarchy above or below the question at issue. Standing on the shoulders of philosophers like Quine and Sellars, Churchland insisted that specifying some point where neuroscience ends and philosophy of science begins is hopeless because the boundaries are poorly defined. Neurophilosophers would pick and choose resources from both disciplines as they saw fit.

Three themes predominate Churchland's philosophical discussion: developing an alternative to the logical empiricist theory of intertheoretic reduction; responding to property-dualistic arguments based on subjectivity and sensory qualia; and responding to anti-reductionist multiple realizability arguments. These projects have remained central to neurophilosophy over the past decade. John Bickle (1998) extends the principal insight of Clifford Hooker's (1981) post-empiricist theory of intertheoretic reduction. He quantifies key notions using a model-theoretic account of theory structure adapted from the structuralist program in philosophy of science (Balzer, Moulines, and Sneed, 1987). He also makes explicit the form of argument scientists employ to draw ontological conclusions (cross-theoretic identities, revisions, or eliminations) based on the nature of the intertheoretic reduction relations obtaining in soecific cases. For example, physicists concluded that visible light, a theoretical posit of optics, is electromagnetic radiation within specified wavelengths, a theoretical posit of electromagnetism: a cross-theoretic ontological identity. In another case, however, chemists concluded that phlogiston did not exist: an elimination of a kind from our scientific ontology. Bickle explicates the nature of the reduction relation in a specific case using a semi-formal account of ‘intertheoretic approximation’ inspired by structuralist results. Paul Churchland (1996) has carried on the attack on property-dualistic arguments for the irreducibility of conscious experience and sensory qualia. He argues that acquiring some knowledge of existing sensory neuroscience increases one's ability to ‘imagine’ or ‘conceive of’ a comprehensive neurobiological explanation of consciousness. He defends this conclusion using a thought-experiment based on the history of optics and electromagnetism. Finally, the literature critical of the multiple realizability argument has begun to flourish. Although the multiple realizability argument remains influential among nonreductive physicalists, it no longer commands the universal acceptance it once did. Replies to the multiple realizability argument based on neuroscientific details have appeared. For example, William Bechtel and Jennifer Mundale (1997, in press) argue that neuroscientists use

psychological criteria in brain mapping studies. This fact undercuts the likelihood that psychological kinds are multiply realized. (For a review of recent developments see the final sections of the entry on 'Multiple Realizability' in this Encyclopedia, linked below.)

Eliminative Materialism and Philosophy Neuralized

Eliminative materialism (EM) is the conjunction of two claims. First, our common sense 'belief-desire' conception of mental events and processes, our 'folk psychology,' is a false and misleading account of the causes of human behavior. Second, like other false conceptual frameworks from both folk theory and the history of science, it will be replaced by, rather than smoothly reduced or incorporated into, a future neuroscience. Folk psychology is the collection of common homilies about the causes of human behavior. You ask me why Marica is not accompanying me this evening. I reply that her grant deadline is looming. You nod sympathetically. You understand my explanation because you share with me a generalization that relates beliefs about looming deadlines, desires about meeting professionally and financially significant ones, and ensuing free-time behavior. It is the collection of these kinds of homilies that EM claims to be flawed beyond significant revision. Although this example involves only beliefs and desires, folk psychology contains an extensive repertoire of propositional attitudes in its explanatory nexus: hopes, intentions, fears, imaginings, and more. To the extent that scientific psychology (and neuroscience!) retains folk concepts, EM applies to it as well.

EM is physicalist in the classical sense, postulating some future brain science as the ultimately correct account of (human) behavior. It is eliminative in predicting the future removal of folk psychological kinds from our post-neuroscientific ontology. EM proponents often employ scientific analogies (Feyerabend 1963; Churchland, 1981). Oxidative reactions as characterized within elemental chemistry bear no resemblance to phlogiston release. Even the "direction" of the two processes differ. Oxygen is gained when an object burns (or rusts), phlogiston was said to be lost. The result of this theoretical change was the elimination of phlogiston from our scientific ontology. There is no such thing. For the same reasons, according to EM, continuing development in neuroscience will reveal that there are no such things as beliefs and desires as characterized by common sense.

Here we focus only on the way that neuroscientific results have shaped the arguments for EM. Surprisingly, only one argument has been strongly influenced. (Most arguments for EM stress the failures of folk psychology as an explanatory theory of behavior.) This argument is based on a development in cognitive and computational neuroscience that might provide a genuine alternative to the representations and computations implicit in folk psychological generalizations. Many eliminative materialists assume that folk psychology is committed to propositional representations and computations over their contents that mimic logical inferences (Paul Churchland, 1981; Stich, 1983; Patricia Churchland, 1986).[2] Even though discovering such an alternative has been an eliminativist goal for some time, neuroscience only began delivering on this goal over the past fifteen years. Points in and trajectories through vector spaces, as an interpretation of synaptic events and neural activity patterns in biological neural networks are key features of this new development. This argument for EM hinges on the differences between these notions of cognitive representation and the propositional attitudes of folk psychology (Churchland, 1987).

However, this argument will be opaque to those with no background in contemporary cognitive and computational neuroscience, so we need to present a few scientific details. With these details in place, we will return to this argument for EM (five paragraphs below).

At one level of analysis the basic computational element of a neural network (biological or artificial) is the neuron. This analysis treats neurons as simple computational devices, transforming inputs into output. Both neuronal inputs and outputs reflect biological variables. For the remainder of this discussion, we will assume that neuronal inputs are frequencies of action potentials (neuronal "spikes") in the axons whose terminal branches synapse onto the neuron in question. Neuronal output is the frequency of action potentials in the axon of the neuron in question. A neuron computes its total input (usually treated mathematically as the sum of the products of the signal strength along each input line times the synaptic weight on that line). It then computes a new activation state based on its total input and current activation state, and a new output state based on its new activation value. The neuron's output state is transmitted as a signal strength to whatever neurons its axon synapses on. The output state reflects systematically the neuron's new activation state.[3]

Analyzed at this level, both biological and artificial neural networks are interpreted naturally as *vector-to-vector transformers*. The input vector consists of values reflecting activity patterns in axons synapsing on the network's neurons from outside (e.g., from sensory transducers or other neural networks). The output vector consists of values reflecting the activity patterns generated in the network's neurons that project beyond the net (e.g., to motor effectors or other neural networks). Given that neurons' activity depends partly upon their total input, and total input depends partly on synaptic weights (e.g., presynaptic neurotransmitter release rate, number and efficacy of postsynaptic receptors, availability of enzymes in synaptic cleft), the capacity of biological networks to change their synaptic weights make them *plastic* vector-to-vector transformers. In principle, a biological network with plastic synapses can come to implement any vector-to-vector transformation that its composition permits (number of input units, output units, processing layers, recurrency, cross-connections, etc.) (Churchland, 1987).

The anatomical organization of the cerebellum provides a clear example of a network amendable to this computational interpretation. Consider Figure 1. The cerebellum is the bulbous convoluted structure dorsal to the brainstem. A variety of studies (behavioral, neuropsychological, single-cell electrophysiological) implicate this structure in motor integration and fine motor coordination. Mossy fibers (axons) from neurons outside the cerebellum synapse on cerebellular granule cells, which in turn project to parallel fibers. Activity patterns across the collection of mossy fibers (frequency of action potentials per time unit in each fiber projecting into the cerebellum) provide values for the input vector. Parallel fibers make multiple synapses on the dendritic trees and cell bodies of cerebellular Purkinje neurons. Each Purkinje neuron "sums" its post-synaptic potentials (PSPs) and emits a train of action potentials down its axon based (partly) on its total input and previous activation state. Purkinje axons project outside the cerebellum. The network's output vector is thus the ordered values representing the pattern of activity generated in each Purkinje axon. Changes to the efficacy of individual synapses on the parallel fibers and the Purkinje neurons alter the resulting PSPs in Purkinje axons, generating different axonal spiking frequencies. Computationally, this amounts to a different output vector to the same input activity pattern (plasticity).[4]

This interpretation puts the useful mathematical resources of *dynamical systems* into the hands of computational neuroscientists. *Vector spaces* are an example. For example, learning can be characterized fruitfully in terms of changes in synaptic weights in the network and subsequent reduction of error in network output. (This approach goes back to Hebb, 1949, although within the vector-space interpretation that follows.) A useful representation of this account is on a *synaptic weight-error space*, where one dimension represents the global error in the network's output to a given task, and all other dimensions represent the weight values of individual synapses in the network. Consider Figure 2. Points in this multi-dimensional state space represent the global performance error correlated with each possible collection of synaptic weights in the network. As the weights change with each performance (in accordance with a biologically-implemented learning algorithm), the global error of network performance continually decreases. Learning is represented as synaptic weight changes correlated with a descent along the error dimension in the space (Churchland and Sejnowski, 1992). Representations (concepts) can be portrayed as *partitions* in multi-dimensional vector spaces. An example is a *neuron activation* vector space. See Figure 3. A graph of such a space contains one dimension for the activation value of each neuron in the network (or some subset). A point in this space represents one possible pattern of activity in all neurons in the network. Activity patterns generated by input vectors that the network has learned to group together will cluster around a (hyper-) point or subvolume in the activity vector space. Any input pattern sufficiently similar to this group will produce an activity pattern lying in geometrical proximity to this point or subvolume. Paul Churchland (1989) has argued that this interpretation of network activity provides a quantitative, neurally-inspired basis for prototype theories of concepts developed recently in cognitive psychology.

Using this theoretical development, Paul Churchland (1987, 1989) has offered a novel argument for EM. According to this approach, activity vectors are the central kind of representation and vector-to-vector transformations are the central kind of computation in the brain. This contrasts sharply with the *propositional* representations and *logical/semantic* computations postulated by folk psychology. Vectorial content is unfamiliar and alien to common sense. This cross-theoretic difference is at least as great as that between oxidative and phlogiston concepts, or kinetic-corpuscular and caloric fluid heat concepts. Phlogiston and caloric fluid are two "parade" examples of kinds eliminated from our scientific ontology due to the nature of the intertheoretic relation obtaining between the theories with which they are affiliated and the theories that replaced these. The structural and dynamic differences between the folk psychological and emerging cognitive neuroscientific kinds suggest that the theories affiliated with the latter will also correct significantly the theory affiliated with the former. This is the key premise of an eliminativist argument based on predicted intertheoretic relations. And these intertheoretic contrasts are no longer just an eliminativist's goal. Computational and cognitive neuroscience has begun to deliver an alternative kinematics for cognition, one that provides no structural analogue for the propositional attitudes.

Certainly the replacement of propositional contents by vectorial alternatives implies significant correction to folk psychology. But does it justify EM? Even though this central feature of folk-psychological posits finds no analogues in one hot theoretical development in recent cognitive and computational neuroscience, there might be other aspects of cognition that folk psychology gets right. Within

neurophilosophy, concluding that a cross-theoretic identity claim is true (e.g., folk psychological state F is identical to neural state N) or that an eliminativist claim is true (there is no such thing as folk psychological state F) depends on the nature of the intertheoretic reduction obtaining between the theories affiliated with the posits in question (Hooker, 1981; Churchland, 1986; Bickle, 1998). But the underlying account of intertheoretic reduction recognizes a spectrum of possible reductions, ranging from relatively "smooth" through "significantly revisionary" to "extremely bumpy".[5] Might the reduction of folk psychology and a "vectorial" neurobiology occupy the middle ground between "smooth" and "bumpy" intertheoretic reductions, and hence suggest a "revisionary" conclusion? The reduction of classical equilibrium thermodynamics to statistical mechanics to microphysics provides a potential analogy. John Bickle (1992, 1998, chapter 6) argues on empirical grounds that such a outcome is likely. He specifies conditions on "revisionary" reductions from historical examples and suggests that these conditions are obtaining between folk psychology and cognitive neuroscience as the latter develops. In particular, folk psychology appears to have gotten right the grossly-specified functional profile of many cognitive states, especially those closely related to sensory input and behavioral output. It also appears to get right the "intentionality" of many cognitive states--the object that the state is of or about--even though cognitive neuroscience eschews its implicit linguistic explanation of this feature. Revisionary physicalism predicts significant *conceptual change* to folk psychological concepts, but denies total elimination of the caloric fluid-phlogiston variety.

The philosophy of science is another area where vector space interpretations of neural network activity patterns has impacted philosophy. In the Introduction to his (1989) book, Paul Churchland asserts that it will soon be impossible to do serious work in the philosophy of science without drawing on empirical work in the brain and behavioral sciences. To justify this claim, in Part II of the book he suggests neurocomputational reformulations of key concepts from this area. At the heart is a neurocomputational account of the structure of scientific theories (1989, chapter 9). Problems with the orthodox "sets-of-sentences" view have been well-known for over three decades. Churchland advocates replacing the orthodox view with one inspired by the "vectorial" interpretation of neural network activity. Representations implemented in neural networks (as discussed above) compose a system that corresponds to important distinctions in the external environment, are not explicitly represented as such within the input corpus, and allow the trained network to respond to inputs in a fashion that continually reduces error. These are exactly the functions of theories. Churchland is bold in his assertion: an individual's theory-of-the-world is a specific point in that individual's error-synaptic weight vector space. It is a configuration of synaptic weights that partitions the individual's activation vector space into subdivisions that reduce future error messages to both familiar and novel inputs. (Consider again Figure 2 and Figure 3.) This reformulation invites an objection, however. Churchland boasts that his theory of theories is preferable to existing alternatives to the orthodox "sets-of-sentences" account--for example, the *semantic* view (Suppe, 1974; van Fraassen, 1980)--because his is closer to the "buzzing brains" that use theories. But as Bickle (1993) notes, neurocomputational models based on the mathematical resources described above are a long way into the realm of abstractia. Even now, they remain little more than novel (and suggestive) applications of the mathematics of quasi-linear dynamical systems to simplified schemata of brain circuitries. Neurophilosophers owe some account of identifications across ontological categories before the philosophy of science community will accept the claim that theories are points in high-dimensional state spaces implemented in biological neural networks. (There is an important

methodological assumption lurking in this objection, however, which we will discuss toward the end of the next paragraph.)

Churchland's neurocomputational reformulations of scientific and epistemological concepts build on this account of theories. He sketches "neuralized" accounts of the theory-ladenness of perception, the nature of concept unification, the virtues of theoretical simplicity, the nature of Kuhnian paradigms, the kinematics of conceptual change, the character of abduction, the nature of explanation, and even moral knowledge and epistemological normativity. Conceptual redeployment, for example, is the activation of an already-existing prototype representation--the centerpoint or region of a partition of a high-dimensional vector space in a trained neural network--to a novel type of input pattern. Obviously, we can't here do justice to Churchland's many and varied attempts at reformulation. We urge the intrigued reader to examine his suggestions in their original form. But a word about philosophical methodology is in order. Churchland is *not* attempting "conceptual analysis" in anything resembling its traditional philosophical sense and neither, typically, are neurophilosophers.(This is why a discussion of neurophilosophical reformulations fits with a discussion of EM.) There are philosophers who take the discipline's ideal to be a relatively simple set of necessary and sufficient conditions, expressed in non-technical natural language, governing the application of important concepts (like justice, knowledge, theory, or explanation). These analyses should square, to the extent possible, with pretheoretical usage. Ideally, they should preserve synonymy. Other philosophers view this ideal as sterile, misguided, and perhaps deeply mistaken about the underlying structure of human knowledge (Ramsey, 1992). Neurophilosophers tend to reside in the latter camp. Those who dislike philosophical speculation about the promise and potential of nascent science in an effort to reformulate ("*reform*-ulate") traditional philosophical concepts have probably already discovered that neurophilosophy is not for them. But the charge that neurocomputational reformulations of the sort Churchland attempts are "philosophically uninteresting" or "irrelevant" because they fail to provide "adequate analyses" of theory, explanation, and the like will fall on deaf ears among many contemporary philosophers, as well as their cognitive-scientific and neuroscientific friends.

Before we leave the neurophilosophical applications of this theoretical development from recent cognitive/computational neuroscience, one more point of scientific detail is in order. The popularity of treating the neuron as the basic computational unit among *neural* modelers, as opposed to cognitive modelers, is declining rapidly. *Compartmental modeling* enables computational neuroscientists to mimic activity in and interactions between patches of neuronal membrane (Bower and Beeman, 1995). This permits modelers to control and manipulate a variety of subcellular factors that determine action potentials per time unit (including the topology of membrane structure in individual neurons, variations in ion channels across membrane patches, field properties of post-synaptic potentials depending on the location of the synapse on the dendrite or soma). Modelers can "custom build" the neurons in their target circuitry without sacrificing the ability to study circuit properties of networks. For these reasons, few serious computational *neuro*scientists continue to work at a level that treats neurons as unstructured computational devices. But the above interpretative points still stand. With compartmental modeling, not only are simulated neural networks interpretable as vector-to-vector transformers. The neurons composing them are, too.

Philosophy of science and scientific epistemology are not the only areas where philosophers have lately urged the relevance of neuroscientific discoveries. Kathleen Akins (1996) argues that a "traditional" view of the senses underlies the variety of sophisticated "naturalistic" programs about intentionality. (She cites the Churchlands, Daniel Dennett, Fred Dretske, Jerry Fodor, David Papineau, Dennis Stampe, and Kim Sterelny as examples, with extensive references.) Current neuroscientific understanding of the mechanisms and coding strategies implemented by sensory receptors shows that this traditional view is mistaken. The traditional view holds that sensory systems are "veridical" in at least three ways. (1) Each signal in the system correlates with a small range of properties in the external (to the body) environment. (2) The structure in the relevant relations between the external properties the receptors are senstive to is preserved in the structure of the relations between the resulting sensory states. And (3) the sensory system reconstructs faithfully, without fictive additions or embellishments, the external events. Using recent neurobiological discoveries about response properties of thermal receptors in the skin as an illustration, Akins shows that sensory systems are "narcissistic" rather than "veridical." All three traditional assumptions are violated. These neurobiological details and their philosophical implications open novel questions for the philosophy of perception and for the appropriate foundations for naturalistic projects about intentionality. Armed with the known neurophysiology of sensory receptors, for example, our "philosophy of perception" or of "perceptual intentionality" will no longer focus on the search for correlations between states of sensory systems and "veridically detected" external properties. This traditional philosophical (and scientific!) project rests upon a mistaken "veridical" view of the senses. Neuroscientific knowledge of sensory receptor activity also shows that sensory experience does not serve the naturalist well as a "simple paradigm case" of an intentional relation between representation and world. Once again, available scientific detail shows the naivity of some traditional philosophical projects.

Focusing on the anatomy and physiology of the pain transmission system, Valerie Hardcastle (1997) urges a similar negative implication for a popular methodological assumption. Pain experiences have long been philosophers' favorite cases for analysis and theorizing about conscious experience generally. Nevertheless, every position about pain experiences has been defended recently: eliminativism, a variety of objectivist views, relational views, and subjectivist views. Why so little agreement, despite agreement that pain experiences are the place to start an analysis or theory of consciousness? Hardcastle urges two answers. First, philosophers tend to be uninformed about the neuronal complexity of our pain transmission systems, and build their analyses or theories on the outcome of a single component of a multi-component system. Second, even those who understand some of the underlying neurobiology of pain tend to advocate gate-control theories.[6] But the best existing gate-control theories are vague about the neural mechanisms of the gates. Hardcastle instead proposes a dissociable dual system of pain transmission, consisting of a pain sensory system closely analogous in its neurobiological implementation to other sensory systems, and a descending pain inhibitory system. She argues that this dual system is consistent with recent neuroscientific discoveries and accounts for all the pain phenomena that have tempted philosophers toward particular (but limited) theories of pain experience. The neurobiological uniqueness of the pain inhibitory system, contrasted with the mechanisms of other sensory modalities, renders pain processing atypical. In particular, the pain inhibitory system dissociates pain sensation from stimulation of nociceptors (pain receptors). Hardcastle concludes from the neurobiological uniqueness of pain transmission that pain experiences are atypical conscious events, and hence not a good place to start theorizing about or analyzing the general type.

Neuroscience and Psychosemantics

Developing and defending theories of content is a central topic in current philosophy of mind. A common desideratum in this debate is a theory of cognitive representation consistent with a physical or naturalistic ontology. We'll here describe a few contributions neurophilosophers have made to this literature.

When one perceives or remembers that he is out of coffee, his brain state possesses intentionality or "aboutness." The percept or memory is about one's being out of coffee; it represents one as being out of coffee. The representational state has content. A psychosemantics seeks to explain what it is for a representational state to be about something: to provide an account of how states and events can have specific representational content. A physicalist psychosemantics seeks to do this using resources of the physical sciences exclusively. Neurophilosophers have contributed to two types of physicalist psychosemantics: the Functional Role approach and the Informational approach.

The core claim of a functional role semantics holds that a representation has its content in virtue of relations it bears to other representations. Its paradigm application is to concepts of truth-functional logic, like the conjunctive ‘and’ or disjunctive ‘or.’ A physical event instantiates the ‘and’ function just in case it maps two true inputs onto a single true output. Thus it is the relations an expression bears to others that give it the semantic content of ‘and.’ Proponents of functional role semantics propose similar analyses for the content of all representations (Block 1986). A physical event represents birds, for example, if it bears the right relations to events representing feathers and others representing beaks. By contrast, informational semantics ascribe content to a state depending upon the causal relations obtaining between the state and the object it represents. A physical state represents birds, for example, just in case an appropriate causal relation obtains between it and birds. At the heart of informational semantics is a causal account of information (Dretske, 1981, 1988). Red spots on a face carry the information that one has measles because the red spots are caused by the measles virus. A common criticism of informational semantics holds that mere causal covariation is insufficient for representation, since information (in the causal sense) is by definition always veridical while representations can misrepresent. A popular solution to this challenge invokes a teleological analysis of ‘function.’ A brain state represents X by virtue of having the function of carrying information about being caused by X (Dretske 1988). These two approaches do not exhaust the popular options for a psychosemantics, but are the ones to which neurophilosophers have contributed.

Paul Churchland's allegiance to functional role semantics goes back to his earliest views about the semantics of terms in a language. In his (1979) book, he insists that the semantic identity (content) of a term derives from its place in the network of sentences of the entire language. The functional economies envisioned by early functional role semanticists were networks with nodes corresponding to the objects and properties denoted by expressions in a language. Thus one node, appropriately connected, might represent birds, another feathers, and another beaks. Activation of one of these would tend to spread to the others. As ‘connectionist’ network modeling developed, alternatives arose to this one-representation-per-node ‘localist’ approach. By the time Churchland (1989) provided a neuroscientific elaboration of functional role semantics for cognitive representations generally, he too had abandoned the ‘localist’

interpretation. Instead, he offered a 'state-space semantics'.

We saw in the section just above how (vector) state spaces provide a natural interpretation for activity patterns in neural networks (biological and artificial). A state-space semantics for cognitive representations is a species of a functional role semantics because the individuation of a particular state depends upon the relations obtaining between it and other states. A representation is a point in an appropriate state space, and points (or subvolumes) in a space are individuated by their relations to other points (locations, geometrical proximity). Churchland (1989, 1995) illustrates a state-space semantics for neural states by appealing to sensory systems. One popular theory in sensory neuroscience of how the brain codes for sensory qualities (like color) is the *opponent process account* (Hardin 1988). Churchland (1995) describes a three-dimensional activation vector state-space in which every color perceivable by humans is represented as a point (or subvolume). Each dimension corresponds to activity rates in one of three classes of photoreceptors present in the human retina and their efferent paths: the red-green opponent pathway, yellow-blue opponent pathway, and black-white (contrast) opponent pathway. Photons striking the retina are transduced by the receptors, producing an activity rate in each of the segregated pathways. A represented color is hence a triplet of activation frequency rates. As an illustration, consider again Figure 3. Each dimension in that three-dimensional space will represent average frequency of action potentials in the axons of one class of ganglion cells projecting out of the retina. Each color perceivable by humans will be a region of that space. For example, an orange stimulus produces a relatively low level of activity in both the red-green and yellow-blue opponent pathways (x-axis and y-axis, respectively), and middle-range activity in the black-white (contrast) opponent pathway (z-axis). Pink stimuli, on the other hand, produce low activity in the red-green opponent pathway, middle-range activity in the yellow-blue opponent pathway, and high activity in the black-white (contrast) opponent pathway.[7] The location of each color in the space generates a 'color solid.' Location on the solid and geometrical proximity between regions reflect structural similarities between the perceived colors. Human gustatory representations are points in a four-dimensional state space, with each dimension coding for activity rates generated by gustatory stimuli in each type of taste receptor (sweet, salty, sour, bitter) and their segregated efferent pathways. When implemented in a neural network with structural and hence computational resources as vast as the human brain, the state space approach to psychosemantics generates a theory of content for a huge number of cognitive states.[8]

Jerry Fodor and Ernest LePore (1992) raise an important challenge to Churchland's psychosemantics. Location in a state space alone seems insufficient to fix a state's representational content. Churchland never explains why a point in a three-dimensional state space represents a *color*, as opposed to any other quality, object, or event that varies along three dimensions.[9]. Churchland's account achieves its explanatory power by the interpretation imposed on the dimensions. Fodor and LePore allege that Churchland never specifies how a dimension comes to represent, e.g., degree of saltiness, as opposed to yellow-blue wavelength opposition. One obvious answer appeals to the stimuli that form the 'external' inputs to the neural network in question. Then, for example, the individuating conditions on neural representations of colors are that opponent processing neurons receive input from a specific class of photoreceptors. The latter in turn have electromagnetic radiation (of a specific portion of the visible spectrum) as their activating stimuli. However, this appeal to 'external' stimuli as the ultimate individuating conditions for representational content makes the resulting approach a version of

informational semantics. Is this approach consonant with other neurobiological details?

The neurobiological paradigm for informational semantics is the *feature detector*: one or more neurons that are (i) maximally responsive to a particular type of stimulus, and (ii) have the function of indicating the presence of that stimulus type. Examples of such stimulus-types for visual feature detectors include high-contrast edges, motion direction, and colors. A favorite feature detector among philosophers is the alleged fly detector in the frog. Lettvin *et al*. (1959) identified cells in the frog retina that responded maximally to small shapes moving across the visual field. The idea that these cells' activity functioned to detect flies rested upon knowledge of the frogs' diet. (Bechtel 1998 provides a useful discussion.) Using experimental techniques ranging from single-cell recording to sophisticated functional imaging, neuroscientists have recently discovered a host of neurons that are maximally responsive to a variety of stimuli. However, establishing condition (ii) on a feature detector is much more difficult. Even some paradigm examples have been called into question. David Hubel and Torsten Wiesel's (1962) Nobel Prize-winning work establishing the receptive fields of neurons in striate cortex is often interpreted as revealing cells whose function is edge detection. However, Lehky and Sejnowski (1988) have challenged this interpretation. They trained an artificial neural network to distinguish the three-dimensional shape and orientation of an object from its two-dimensional shading pattern. Their network incorporates many features of visual neurophysiology. Nodes in the trained network turned out to be maximally responsive to edge contrasts, but did not appear to have the function of edge detection. (See Churchland and Sejnowski 1992 for a review.)

Kathleen Akins (1996) offers a different neurophilosophical challenge to informational semantics and its affiliated feature-detection view of sensory representation. We saw in the previous section how Akins argues that the physiology of thermoreception violates three necessary conditions on ‘veridical’ representation. From this fact she draws doubts about looking for feature detecting neurons to ground a psychosemantics generally, including thought contents. Human thoughts about flies, for example, are sensitive to numerical distinctions between particular flies and the particular locations they can occupy. But the ends of frog nutrition are well served without a representational system sensitive to such ontological refinements. Whether a fly seen now is numerically identical to one seen a moment ago need not, and perhaps cannot, figure into the frog's feature detection repertoire. Akins' critique casts doubt on whether details of sensory transduction will scale up to provide an adequate unified psychosemantics. It also raises new questions for human intentionality. How do we get from activity patterns in "narcissistic" sensory receptors, keyed not to "objective" environmental features but rather only to effects of the stimuli on the patch of tissue innervated, to the human ontology replete with enduring objects with stable configurations of properties and relations, types and their tokens (as the "fly-thought" example presented above reveals), and the rest? And how did the development of a stable, rich ontology confer survival advantages to human ancestors?

Consciousness Explained?

Consciousness has re-emerged as a topic in philosophy of mind and the cognitive and brain sciences over the past three decades. Instead of ignoring it, many physicalists now seek to explain it (Dennett, 1991).

Here we focus exclusively on ways that neuroscientific discoveries have impacted philosophical debates about the nature of consciousness and its relation to physical mechanisms. (See links to other entries in this encyclopedia below for broader discussions about consciousness and physicalism.)

Thomas Nagel (1974) argues that conscious experience is subjective, and thus permanently recalcitrant to objective scientific understanding. He invites us to ponder 'what it is like to be a bat' and urges the intuition that no amount of physical-scientific knowledge (including neuroscientific) supplies a complete answer. Nagel's intuition pump has generated extensive philosophical discussion. At least two well-known replies make direct appeal to neurophysiology. John Biro (1991) suggests that part of the intuition pumped by Nagel, that bat experience is substantially different from human experience, presupposes systematic relations between physiology and phenomenology. Kathleen Akins (1993a) delves deeper into existing knowledge of bat physiology and reports much that is pertinent to Nagel's question. She argues that many of the questions about bat subjectivity that we still consider open hinge on questions that remain unanswered about neuroscientific details. One example of the latter is the function of various cortical activity profiles in the active bat.

More recently philosopher David Chalmers (1996) has argued that any possible brain-process account of consciousness will leave open an 'explanatory gap' between the brain process and properties of the conscious experience.[10] This is because no brain-process theory can answer the "hard" question: Why should that particular brain process give rise to conscious experience? We can always imagine ("conceive of") a universe populated by creatures having those brain processes but completely lacking conscious experience. A theory of consciousness requires an explanation of how and why some brain process causes consciousness replete with all the features we commonly experience. The fact that the hard question remains unanswered shows that we will probably never get a complete explanation of consciousness at the level of neural mechanism. Paul and Patricia Churchland (1997) have recently offered the following diagnosis and reply. Chalmers offers a *conceptual argument*, based on our ability to imagine creatures possessing brains like ours but wholly lacking in conscious experience. But the more one learns about how the brain produces conscious experience--and a literature is beginning to emerge (e.g., Gazzaniga, 1995)--the harder it becomes to imagine a universe consisting of creatures with brain processes like ours but lacking consciousness. This is not just bare assertion. The Churchlands appeal to some neurobiological detail. For example, Paul Churchland (1995) develops a neuroscientific account of consciousness based on recurrent connections between thalamic nuclei (particularly "diffusely projecting" nuclei like the intralaminar nuclei) and cortex.[11] Churchland argues that the thalamocortical recurrency accounts for the selective features of consciousness, for the effects of short-term memory on conscious experience, for vivid dreaming during REM (rapid-eye movement) sleep, and other "core" features of conscious experience. In other words, the Churchlands are claiming that when one learns about activity patterns in these recurrent circuits, one can't "imagine" or "conceive of" this activity occurring without these core features of conscious experience. (Other than just mouthing the words, "I am now imagining activity in these circuits without selective attention/the effects of short-term memory/vivid dreaming/...").

A second focus of skeptical arguments about a complete neuroscientific explanation of consciousness is sensory *qualia*: the introspectable qualitative aspects of sensory experience, the features by which subjects discern similarities and differences among their experiences. The colors of visual sensations are a

philosopher's favorite example. One famous puzzle about color qualia is the alleged conceivability of spectral inversions. Many philosophers claim that it is conceptually possible (if perhaps physically impossible) for two humans not to differ neurophysiologically, while the color that fire engines and tomatoes appear to have to one subject is the color that grass and frogs appear to have to the other (and vice versa). A large amount of neuroscientifically-informed philosophy has addressed this question. (C.L. Hardin 1988 and Austen Clark 1993 are noteworthy examples.) A related area where neurophilosophical considerations have emerged concerns the metaphysics of colors themselves (rather than color experiences). A longstanding philosophical dispute is whether colors are objective properties existing external to perceivers or rather identifiable as or dependent upon minds or nervous systems. Some recent work on this problem begins with characteristics of color experiences: for example, that color similarity judgments produce color orderings that align on a circle (Clark 1993). With this resource, one can seek mappings of phenomenology onto environmental or physiological regularities. Identifying colors with particular frequencies of electromagnetic radiation does not preserve the structure of the hue circle, whereas identifying colors with activity in opponent processing neurons does. Such a tidbit is not decisive for the color objectivist-subjectivist debate, but it does convey the type of neurophilosophical work being done on traditional metaphysical issues beyond the philosophy of mind. (For more details on these issues, see the entry on Color in this Encyclopedia, linked below.)

We saw in the discussion of Hardcastle (1997) two sections above that neurophilosophers have entered disputes about the nature and methodological import of pain experiences. Two decades earlier, Dan Dennett (1978) took up the question of whether it is possible to build a computer that feels pain. He compares and notes tension between neurophysiological discoveries and common sense intuitions about pain experience. He suspects that the incommensurability between scientific and common sense views is due to incoherence in the latter. His attitude is wait-and-see. But foreshadowing Churchland's reply to Chalmers, Dennett favors scientific investigations over conceivability-based philosophical arguments.

Neurological deficits have attracted philosophical interest. For thirty years philosophers have found implications for the unity of the self in experiments with commissurotomy patients (Nagel 1971).[12] In carefully controlled experiments, commissurotomy patients display two dissociable seats of consciousness. In chapter 5 of her (1986) book, Patricia Churchland scouts philosophical implications of a variety of neurological deficits. One deficit is blindsight. Some patients with lesions to primary visual cortex report being unable to see items in regions of their visual fields, yet perform far better than chance in forced guess trials about stimuli in those regions. A variety of scientific and philosophical interpretations have been offered. Ned Block (1988) worries that many of these conflate distinct notions of consciousness. He labels these notions ‘phenomenal consciousness’ (‘P-consciousness’) and ‘access consciousness’ (‘A-consciousness’). The former is the ‘what it is like’-ness of experience. The latter is the availability of representational content to self-initiated action and speech. Block argues that P-consciousness is not always representational whereas A-consciousness is. Dennett (1991, 1995) and Michael Tye (1993) are skeptical of non-representational analyses of consciousness in general. They provide accounts of blindsight that do not depend on Block's distinction.

We break off our brief overview of neurophilosophical work on consciousness here. Many other topics are worth neurophilosophical pursuit. We mentioned commissurotomy and the unity of consciousness and

the self, which continues to generate discussion. Qualia beyond those of color and pain have begun to attract neurophilosophical attention (Akins 1993a, 1993b, 1996; Clark 1993), as has self-consciousness (Bermudez 1998).

Location of Cognitive Function: From Lesion Studies to Recent Neuroimaging

One of the first issues to arise in the 'philosophy of neuroscience' (before there was a recognized area) was the localization of cognitive functions to specific neural regions. Although the 'localization' approach had dubious origins in the phrenology of Gall and Spurzheim, and was challenged severely by Flourens throughout the early nineteenth century, it re-emerged in the study of aphasia by Bouillaud, Auburtin, Broca, and Wernicke. These neurologists made careful studies (where possible) of linguistic deficits in their aphasic patients followed by brain autopsies post mortem.[13] Broca's initial study of twenty-two patients in the mid-nineteenth century confirmed that damage to the *left cortical hemisphere* was predominant, and that damage to the second and third frontal convolutions was necessary to produce speech production deficits. Although the anatomical coordinates Broca postulated for the 'speech production center'' do not correlate exactly with damage producing production deficits, both this area of frontal cortex and speech production deficits still bear his name ('Broca's area' and 'Broca's aphasia'). Less than two decades later Carl Wernicke published evidence for a second language center. This area is anatomically distinct from Broca's area, and damage to it produced a very different set of aphasic symptoms. The cortical area that still bears his name ('Wernicke's area') is located around the first and second convolutions in temporal cortex, and the aphasia that bears his name ('Wernicke's aphasia') involves deficits in language comprehension. Wernicke's method, like Broca's, was based on lesion studies: a careful evaluation of the behavioral deficits followed by post mortem examination to find the sites of tissue damage and atrophy. Lesion studies suggesting more precise localization of specific linguistic functions remain a cornerstone to this day in aphasic research.

Lesion studies have also produced evidence for the localization of other cognitive functions: for example, sensory processing and certain types of learning and memory. However, localization arguments for these other functions invariably include studies using animal models. With an animal model, one can perform careful behavioral measures in highly controlled settings, then ablate specific areas of neural tissue (or use a variety of other techniques to block or enhance activity in these areas) and remeasure performance on the same behavioral tests. But since we lack an animal model for (human) language production and comprehension, this additional evidence isn't available to the neurologist or neurolinguist. This fact makes the study of language a paradigm case for evaluating the logic of the lesion/deficit method of inferring functional localization. Philosopher Barbara Von Eckardt (1978) attempts to make explicit the steps of reasoning involved in this common and historically important method. Her analysis begins with Robert Cummins' early analysis of functional explanation, but she extends it into a notion of *structurally adequate* functional analysis. These analyses break down a complex capacity C into its constituent capacities c_1, c_2, . . ., c_n, where the constituent capacities are consistent with the underlying structural details of the system. For example, human speech production (complex capacity C) results from

formulating a speech intention, then selecting appropriate linguistic representations to capture the content of the speech intention, then formulating the motor commands to produce the appropriate sounds, then communicating these motor commands to the appropriate motor pathways (constituent capacities c_1, c_2, . . ., c_n). A functional-localization hypothesis has the form: brain structure S in organism (type) O has constituent capacity c_i, where c_i is a function of some part of O. An example might be: Broca's area (S) in humans (O) formulates motor commands to produce the appropriate sounds (one of the constituent capacities c_i). Such hypotheses specify aspects of the structural realization of a functional-component model. They are part of the theory of the neural realization of the functional model.

Armed with these characterizations, Von Eckardt argues that inference to a functional-localization hypothesis proceeds in two steps. First, a functional deficit in a patient is hypothesized based on the abnormal behavior the patient exhibits. Second, localization of function in normal brains is inferred on the basis of the functional deficit hypothesis plus the evidence about the site of brain damage. The structurally-adequate functional analysis of the capacity connects the pathological behavior to the hypothesized functional deficit. This connection suggests four adequacy conditions on a functional deficit hypothesis. First, the pathological behavior P (e.g., the speech deficits characteristic of Broca's aphasia) must result from failing to exercise some complex capacity C (human speech production). Second, there must be a structurally-adequate functional analysis of how people exercise capacity C that involves some constituent capacity c_i (formulating motor commands to produce the appropriate sounds). Third, the operation of the steps described by the structurally-adequate functional analysis minus the operation of the component performing c_i (Broca's area) must result in pathological behavior P. Fourth, there must not be a better available explanation for why the patient does P. Arguments to a functional deficit hypothesis on the basis of pathological behavior is thus an instance of argument to the best available explanation. When postulating a deficit in a normal functional component provides the best available explanation of the pathological data, we are justified in drawing the inference.

Von Eckardt applies this analysis to a neurological case study involving a controversial reinterpretation of agnosia.[14] Her philosophical explication of this important neurological method reveals that most challenges to localization arguments either argue only against the localization of a particular type of functional capacity or against generalizing from localization of function in one individual to all normal individuals. (She presents examples of each from the neurological literature.) Such challenges do not impugn the validity of standard arguments for functional localization from deficits. It does not follow that such arguments are unproblematic. But they face difficult factual and methodological problems, not logical ones. Furthermore, the analysis of these arguments as involving a type of functional analysis and inference to the best available explanation carries an important implication for the biological study of cognitive function. Functional analyses require functional theories, and structurally adequate functional analyses require checks imposed by the lower level sciences investigating the underlying physical mechanisms. Arguments to best available explanation are often hampered by a lack of theoretical imagination: the available explanations are often severely limited. We must seek theoretical inspiration from any level of theory and explanation. Hence making explicit the ‘logic’ of this common and historically important form of neurological explanation reveals the necessity of joint participation from all scientific levels, from cognitive psychology down to molecular neuroscience. Von Eckardt (1978)

anticipated what came to be heralded as the 'co-evolutionary research methodology,' which remains a centerpiece of neurophilosophy to the present day.

Over the last two decades, evidence for localization of cognitive function has come increasingly from a new source: the development and refinement of neuroimaging techniques. The form of localization-of-function argument appears not to have changed from that employing lesion studies (as analyzed by Von Eckardt). Instead, these imaging technologies resolve some of the methodological problems that plauge lesion studies. For example, researchers do not need to wait until the patient dies, and in the meantime probably acquires additional brain damage, to find the lesion sites. Two functional imaging techniques are prominent: positron emission tomography, or PET, and functional magnetic resonance imaging, or fMRI. Although these measure different biological markers of functional activity, both now have a resolution down to around 1mm.[15] As these techniques increase spatial and temporal resolution of functional markers and continue to be used with sophisticated behavioral methodologies, the possibility of localizing specific psychological functions to increasingly specific neural regions continues to grow.[16]

A Result of the Co-evolutionary Research Ideology: Cognitive and Computational Neuroscience

What we now know about the cellular and molecular mechanisms of neural conductance and transmission is spectacular. (For those in doubt, simply peruse for five minutes a recent volume of *Society for Neuroscience Abstracts*.) The same evaluation holds for all levels of explanation and theory about the mind/brain: maps, networks, systems, and behavior. This is a natural outcome of increasing scientific specialization. We develop the technology, the experimental techniques, and the theoretical frameworks within specific disciplines to push forward our understanding. Still, a crucial aspect of the total picture gets neglected: the relationship between the levels, the 'glue' that binds knowledge of neuron activity to subcellular and molecular mechanisms, network activity patterns to the activity of and connectivity between single neurons, and behavior to network activity. This problem is especially glaring when we focus on the relationship between 'cognitivist' psychological theories, postulating information-bearing representations and processes operating over their contents, and the activity patterns in networks of neurons. Co-evolution between explanatory levels still seems more like a distant dream rather than an operative methodology.

It is here that some neuroscientists appeal to 'computational' methods (Churchland and Sejnowski 1992). If we examine the way that computational models function in more developed sciences (like physics), we find the resources of *dynamical systems* constantly employed. Global effects (such as large-scale meteorological patterns) are explained in terms of the interaction of 'local' lower-level physical phenomena, but only by dynamical, nonlinear, and often chaotic sequences and combinations. Addressing the interlocking levels of theory and explanation in the mind/brain using computational resources that have worked to bridge levels in more mature sciences might yield comparable results. This methodology is necessarily interdisciplinary, drawing on resources and researchers from a variety of levels, including higher levels like experimental psychology, 'program-writing' and 'connectionist' artificial intelligence,

and philosophy of science.

However, the use of computational methods in neuroscience is not new. Hodgkin, Huxley, and Katz (1952) incorporated values of voltage-dependent potassium conductance they had measured experimentally in the squid giant axon into an equation from physics describing the time evolution of a first-order kinetic process. This equation enabled them to calculate best-fit curves for modeled conductance versus time data that reproduced the S-shaped (sigmoidal) function suggested by their experimental data. Using equations borrowed from physics, Rall (1959) developed the cable model of dendrites. This theory provided an account of how the various inputs from across the dendritic tree interact temporally and spatially to determine the input-output properties of single neurons. It remains influential today, and has been incorporated into the GENESIS software for programming neurally realistic networks (Bower and Beeman 1995). More recently, David Sparks and his colleagues have shown that a vector-averaging model of activity in neurons of superior colliculi correctly predicts experimental results about the amplitude and direction of saccadic eye movements (Lee, Rohrer, and Sparks 1988). Working with a more sophisticated mathematical model, Apostolos Georgopoulos and his colleagues have predicted direction and amplitude of hand and arm movements based on averaged activity of 224 cells in motor cortex. Their predictions have borne out under a variety of experimental tests (Geogopoulos *et al*. 1986). We mention these particular studies only because we are familiar with them. We could multiply examples of the fruitful interaction of computational and experimental methods in neuroscience easily by one-hundred-fold. Many of these extend back before ‘computational neuroscience’ was a recognized research endeavor.

We've already seen one example, the vector transformation account, of neural representation and computation, under active development in cognitive neuroscience. Other approaches using ‘cognitivist’ resources are also being pursued.[17] Many of these projects draw upon ‘cognitivist’ characterizations of the phenomena to be explained. Many exploit ‘cognitivist’ experimental techniques and methodologies. Some even attempt to derive ‘cognitivist’ explanations from cell-biological processes (e.g., Hawkins and Kandel 1984). As Stephen Kosslyn (1997) puts it, cognitive neuroscientists employ the ‘information processing’ view of the mind characteristic of cognitivism without trying to separate it from theories of brain mechanisms. Such an endeavor calls for an interdisciplinary community willing to communicate the relevant portions of the mountain of detail gathered in individual disciplines with interested nonspecialists: not just people willing to confer with those working at related levels, but researchers trained in the methods and factual details of a variety of levels. This is a daunting requirement, but it does offer some hope for philosophers wishing to contribute to future neuroscience. Thinkers trained in both the ‘synoptic vision’ afforded by philosophy and the factual and experimental basis of genuine graduate-level science would be ideally equipped for this task. Recognition of this potential niche has been slow among graduate programs in philosophy, but there is some hope that a few programs are taking steps to fill it. (See, e.g., "Other Internet Resources," linked below.)

Stanford Encyclopedia of Philosophy
Notes to Philosophy of Neuroscience

Notes

1. See Bickle 1995 and 1998, Chapter 5, and Schaffner 1992 for non-technical overviews emphasizing consequence for the intertheoretic reducibility of cognitive psychology to neuroscience.

2. This assumption is not gratuitous. We saw in the first paragraph of this section that folk psychological generalizations advert to a variety of propositional attitudes. Eliminativists are also not the only theorists who make this assumption. Incarnations of Jerry Fodor's (1981, 1987) influential (and noneliminative) Representational Theory of Mind assume explicitly this account of folk psychology. There have been dissenters, however: Horgan and Graham, 1991 and Jackson and Pettit, 1990.

3. See Rumelhart *et al*., 1986 for an overview of this mathematical framework for parallel distributed processing in artificial systems structured like brains.

4. For a good overview of this circuitry with helpful illustrations, see Llinás, 1975.

5. Hooker, 1981 suggests this terminology. See Bickle 1998, chapter 3 for an attempt to quantify these notions.

6. Gate-control theories hypothesis that the extensive feedback projections in the mammalian pain transmission system serve to inhibit, enhance, or distort feedforward pain information (from nociceptors (pain receptors) to central nervous system). See Hardcastle, 1997 for a critical discussion of these theories, with extensive references.

7. See Churchland, 1995, for an illustration of the location of a number of color stimuli in this space.

8. See Churchland 1989 for an eye-opening approximation of this number.

9. Churchland (1995) himself provides a non-color example of a three-dimensional face space, where the dimensions represent nose width, eye separation, and mouth fullness.

10. For an early articulation of the ‘explanatory gap,’ see Levine 1983.

11. The thalamus is a bilateral structure at the rostral tip of the brainstem. Its various nuclei are densely

connected with cortex.

12. Commissurotomy is a surgical procedure to treat severe epilepsy resistant to other regimes. It involves ablating portions of the corpus callosum, a large band of axon fibers connecting the two cerebral hemispheres.

13. The aphasias are specifically linguistic deficits. They can include, but are not limited to, speech production and speech comprehension deficits. See Kolb and Whishaw, 1996.

14. Agnosia is a recognitional deficit that does not involve specifical sensory deficits. A visual agnosic, for example, can describe features of objects presented visually and even accurately draw the object, but will be unable to identify it (e.g., "rose"); though typically he will be able to identify the object via other sense modalities (olfaction). A prosopagnosic will be able to identify features of faces, but will be unable to identify whose face it is, even if the face has been presented many times. See Kolb and Whishaw (1996) for a good overview. See Sacks (1985) for some clinical descriptions that depict the human side of the deficit.

15. Aside from the potential neurophilosophical impact of being able to image specific neural activity during specific behavioral and cognitive tasks, the underlying science of these techniques is both fascinating and not yet entirely understood. For PET, water or sugar molecules are labeled with unstable radionuclides possessing excessive protons (Magistretti 1999). This extra proton is converted into a neutron by the normal process of radioactive decay. This process emits a positron (a positively-charged electron) which collides with an electron and releases two photons with opposite trajectories. Special detectors located around the head respond to these photons. When two photons simultaneously reach detectors oriented 180 degrees to each other, the positron-electron collision can be localized to a resolution of a few millimeters. Water molecules labeled with oxygen-15 are used to measure amount of blood flow, and deoxyglucose molecules labeled with fluorine-18 are used to measure glucose utilization. Both blood flow and glucose utilization are correlated directly with level of neural and glial cell activity, so a PET scan provides an extremely accurate measure of location of neural activity in baseline and test situations. Sophisticated algorithms and computer graphics produce an image of different activity levels in different neural regions. Activity profiles can be analyzed at a variety of imaged ‘slices’ or ‘cuts’ through the tissue (hence the term, ‘tomography’). Researchers have used PET studies to obtain evidence for, e.g., activity in anterior cingulate cortex as crucial to the executive control of attention (reviewed in Aston-Jones *et al*. 1999). PET technology has also been used extensively to compare and contrast the various neural areas active during distinct linguistic tasks like reading and writing (reviewed in Caplan *et al*. 1999).

fMRI technology provides a way to measure directly the amount of oxygenation or phosphorylation in specific regions of neural tissue (Magistretti 1999). These markers are directly tied to neural activity level since they indicate cell respiration and ATP utilization. Depending on its degree of saturation by oxygen, hemoglobin in the blood alters the signal of biological tissue subjected to a strong magnetic field and then released. Biophysicists still debate the exact mechanisms of these patterns of detectable energy

release. But sensors located around the tissue can convert this energy into coordinates to compute resolution of activity to a few millimeters (roughly equivalent to PET). Although the clinical and experimental applications of this technology are still in their infancy, fMRI has been used to study the localization of specific linguistic functions, memorial functions, and executive and planning functions of frontal cortex.

16. For a useful evaluation and philosophical discussion of PET, seesee Stufflebeam and Bechtel 1997. For further philosophical discussion of localization techniques and arguments see Bechtel and Richardson 1993 and Bechtel and Mundale 1997 and in press.

17. See Llinás and Churchland 1996, especially the essay by Merzenich and deCharms, for the variety of ‘representation’ concepts employed in modern neurobiological theorizing.

FIGURE 1 ARCHITECTURE OF A CEREBELLAR NETWORK

See text for full description (adapted with revisions from Paul Churchland, 1987.)

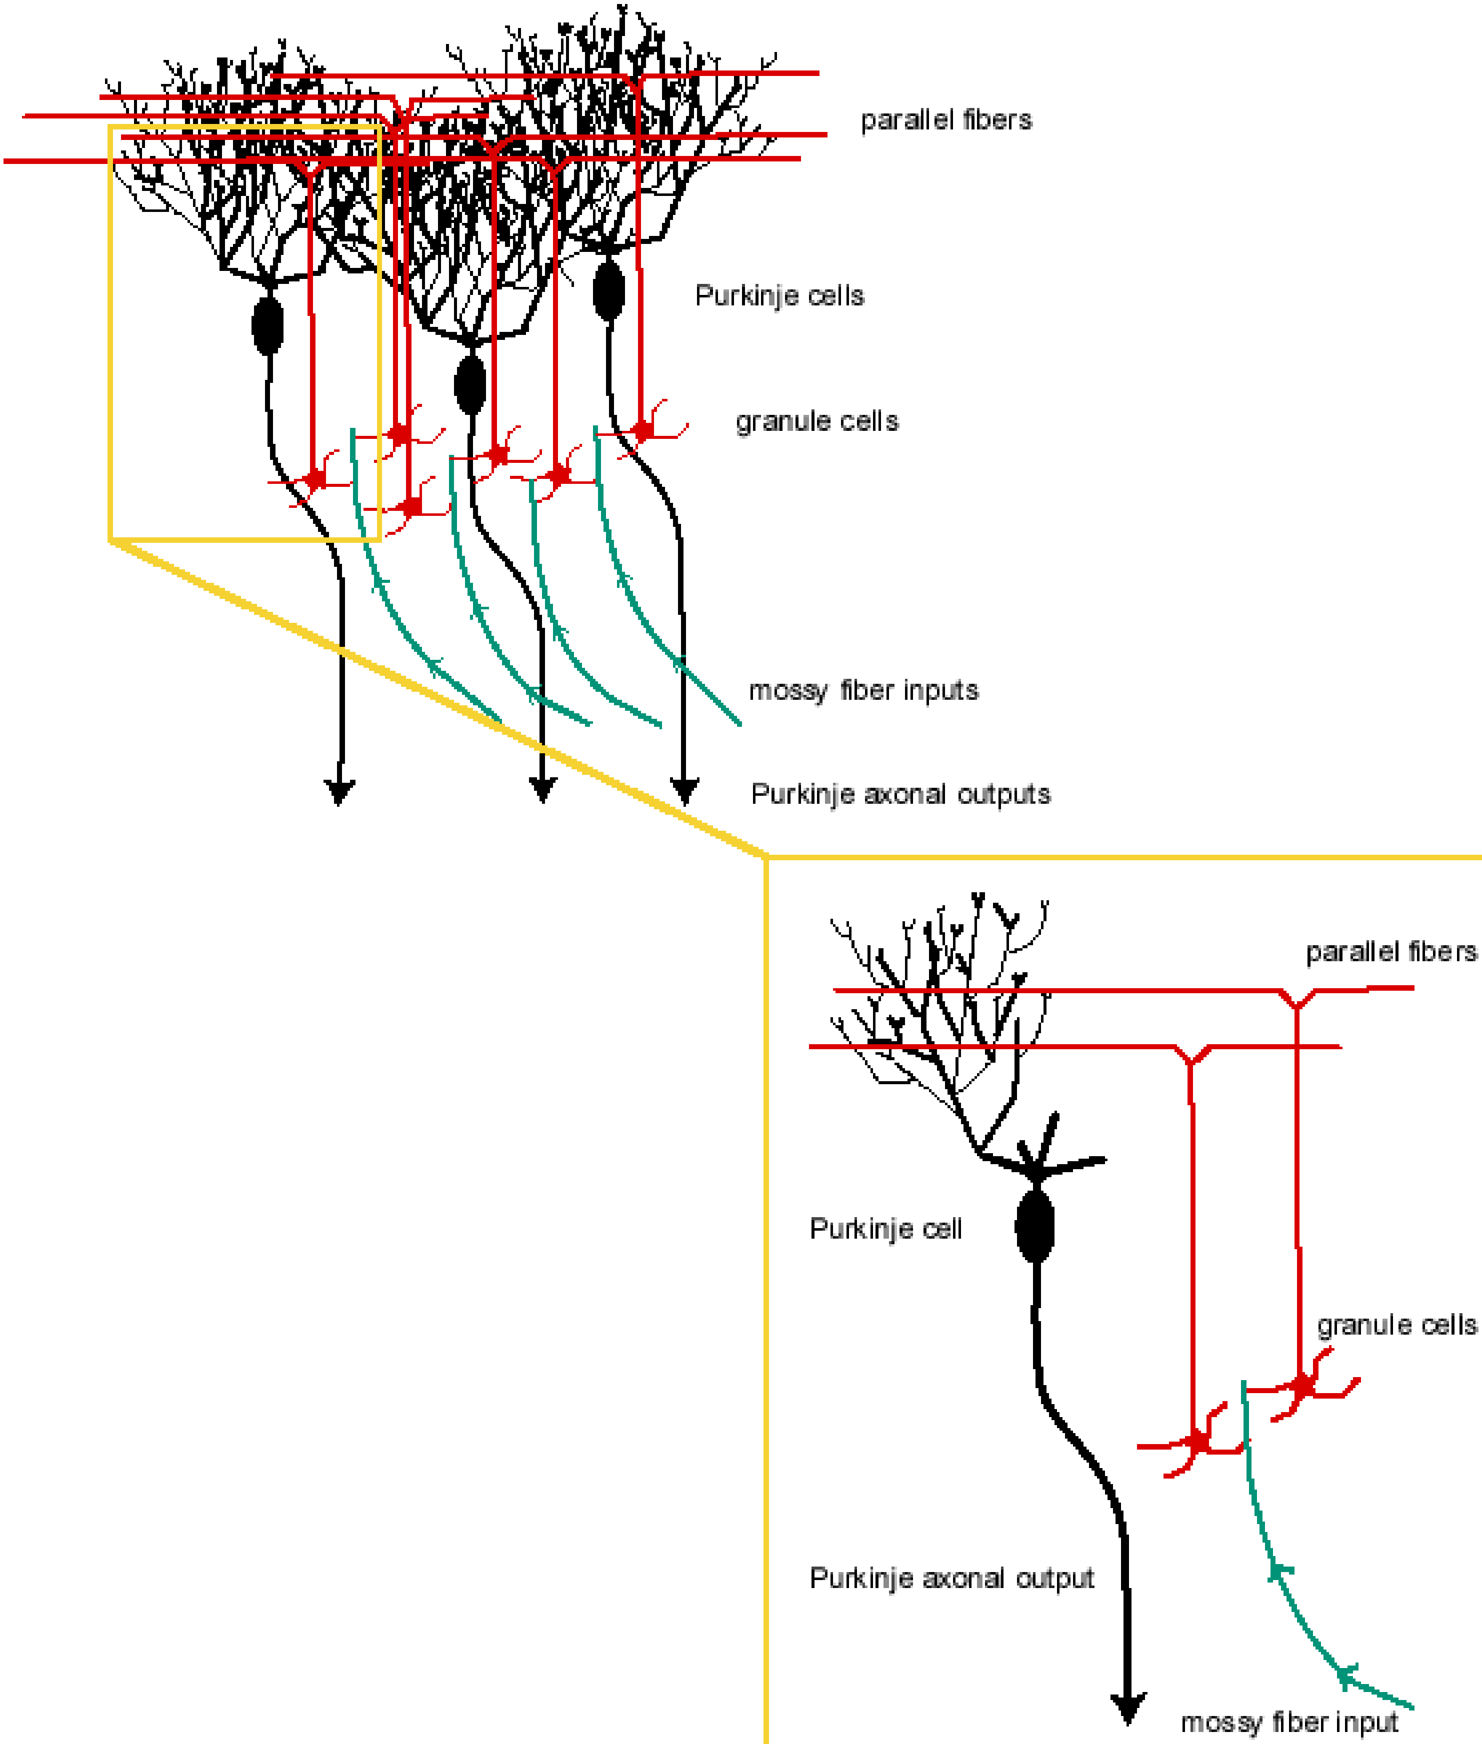

FIGURE 2 LEARNING CHARACTERIZED AS GRADIENT DESCENT IN ERROR-SYNAPTIC WEIGHT SPACE

One axis (y) reflects the global error measure of the network's output to a given input.
The other axes refect weight values of two synapses in the network.
The complete error weight space will have n+1 dimensions, where n is the number of synapses in the network.

See text for full description. (Adapted from Paul Churchland, 1987.)

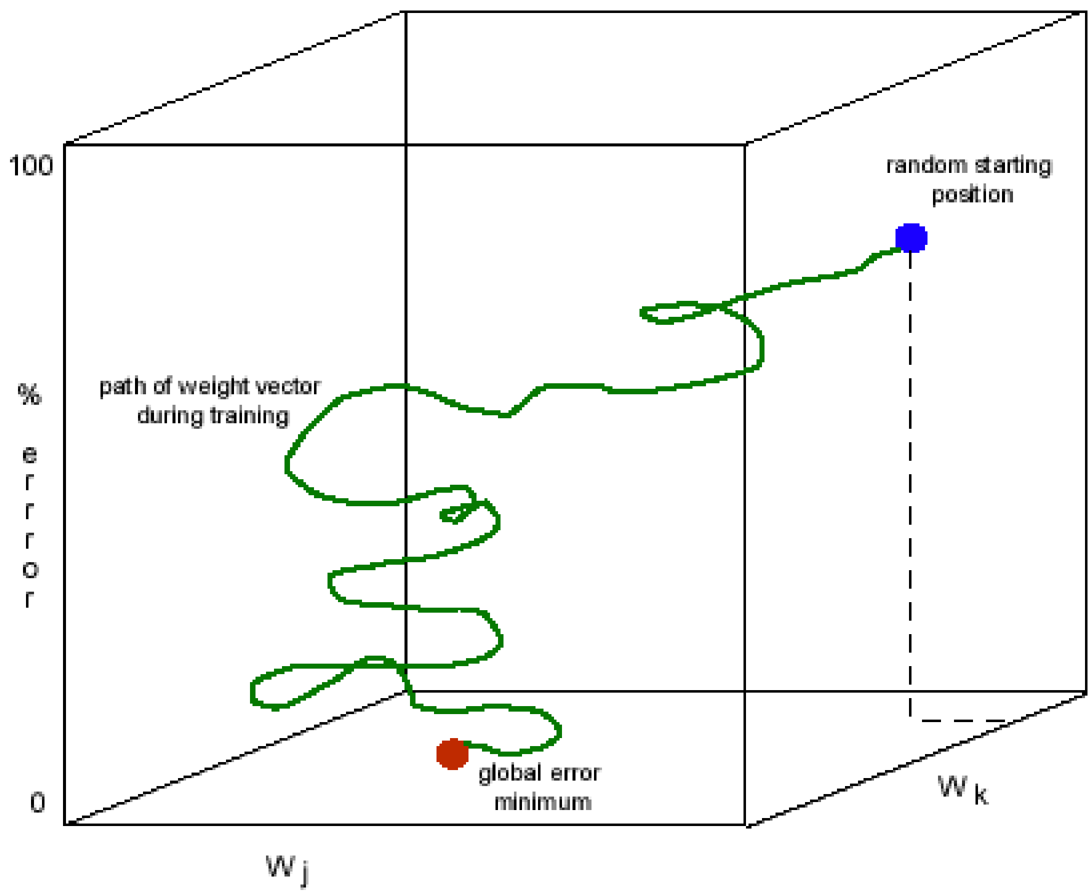

FIGURE 3 REPRESENTATIONAL CONTENT (CONCEPTS) CHARACTERIZED AS PARTITIONS IN HIGH-DIMENSIONAL VECTOR STATE-SPECES

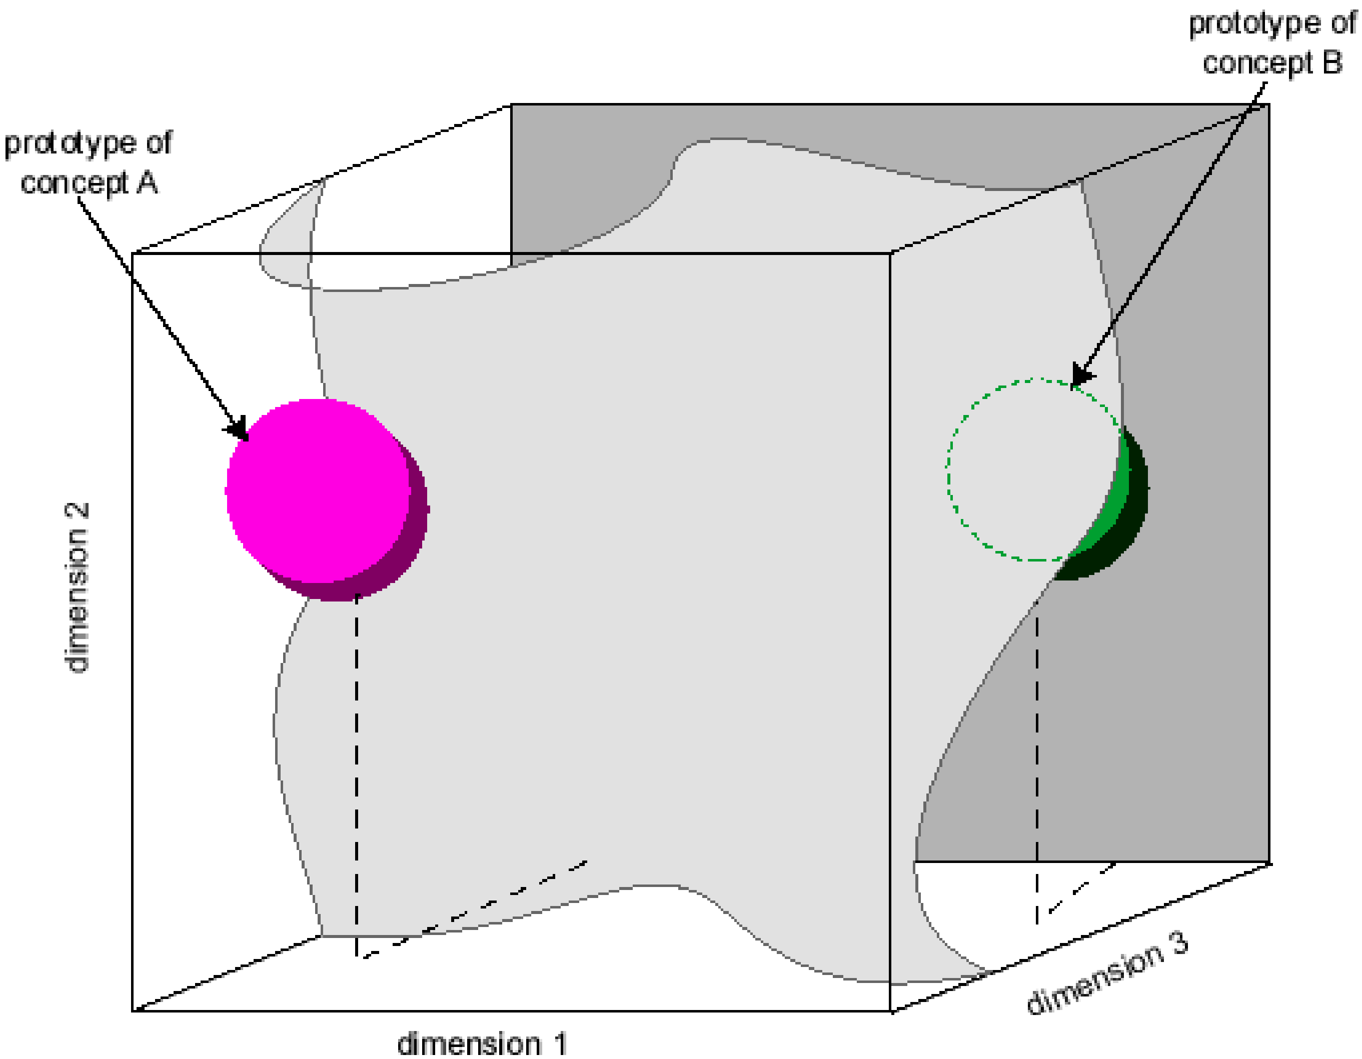
A prototype of the concept is the center point or subvolume in the partition.

See text for full details. (Adapted from paul Churchland, 1989.)



Paul Feyerabend

Paul Feyerabend (b.1924, d.1994), having studied science at the University of Vienna, moved into philosophy for his doctoral thesis, made a name for himself both as an expositor and (later) as a critic of Karl Popper's ‘critical rationalism’, and went on to become one of this century's most famous philosophers of science. An imaginative maverick, he became a critic of philosophy of science itself, particularly of ‘rationalist’ attempts to lay down or discover rules of scientific method.

1. A Brief Chronology of Feyerabend's Life and Work.

1924 Born in Vienna. Son of a civil servant and a seamstress.

1940 Was inducted into the *Arbeitsdienst* (the work service introduced by the Nazis).

1942 Drafted into the Pioneer Corps of the German army. After basic training, volunteered for Officers' School.

1943 Learned of his mother's suicide.

1944 Decorated, Iron Cross. Advanced to Lieutenant. Lectured to Officers' School.

1945 Shot in the spine during the retreat from the Russian Army.

1946 Received a fellowship to study singing and stage-management in Weimar. Joined the ‘Cultural Association for the Democratic Reform of Germany’.

1947 Returned to Vienna to study history and sociology at the University. Soon transferred to physics. First article, on the concept of illustration in modern physics, published. Feyerabend ‘a raving positivist’ at the time.

1948 First visit to the Alpbach seminar of the Austrian College Society. Became secretary of the seminars. Met Karl Popper and Walter Hollitscher. Married first wife, Edeltrud.

1949 Became student leader of the ‘Kraft Circle’, a student philosophy club centred around Viktor Kraft, Feyerabend's dissertation supervisor and a former member of the Vienna Circle. Ludwig Wittgenstein visited the Kraft Circle to give a talk. Feyerabend also met Bertholt Brecht.

1951 Received doctorate in philosophy for his thesis on ‘basic statements’. Applied for a British Council scholarship to study under Wittgenstein at Cambridge. But Wittgenstein died before Feyerabend arrived in England, so Feyerabend chose Popper as his supervisor instead.

1952 Came to England, to study under Popper at the London School of Economics. Concentrated on the quantum theory and Wittgenstein. Studied the typescript of Wittgenstein's *Philosophical Investigations*, and prepared a summary of the book. Befriended another of Popper's students, Joseph Agassi.

1953 Feyerabend returned to Vienna. Popper applied for an extension to his scholarship, but Feyerabend decided to remain in Vienna instead. Translated Popper's *The Open Society and its Enemies* into German. Declined the offer to become Popper's research assistant. Agassi took the post. Feyerabend became research assistant to Arthur Pap in Vienna.

1954 First articles on quantum mechanics and on Wittgenstein published. Pap introduced Feyerabend to Herbert Feigl.

1955 Took up his first full-time academic appointment as lecturer in philosophy at the University of Bristol, England. His summary of Wittgenstein's *Philosophical Investigations* appeared as a review of the book in *The Philosophical Review*.

1956 Married second wife, Mary O'Neill. Published an article on the ‘paradox of analysis’. Feyerabend got to know the quantum physicist David Bohm, whose ideas were to influence him substantially.

1957 Gave a paper on the quantum theory of measurement to the Colston Research Symposium at the University of Bristol.

1958 Took up visiting lectureship at the University of California, Berkeley. Two of his most important early papers, ‘An Attempt at a Realistic Interpretation of Experience’, and ‘Complementarity’ appeared in the proceedings of the Aristotelian Society. In them, Feyerabend argued against positivism and in favour of a scientific realist account of the relation between theory and experience, largely on grounds familiar from Karl Popper's falsificationist views.

1959 Accepted a permanent position at Berkeley, emigrated to the US, becoming a naturalized US citizen.

1960 As a result of earlier discussions with Herbert Feigl, Feyerabend published ‘Das Problem der Existenz theoretischer Entitäten’, in which he argued that there is no special ‘problem’ of theoretical entities, and that *all* entities are hypothetical. Gave two lectures to Oberlin College, Ohio, in which he embroidered on Popper's views about the pre-Socratic thinkers.

1962 ‘Explanation, Reduction, and Empiricism’ appeared. Criticised existing empiricist accounts of explanation and theoretical reduction (Hempel, Nagel), and introduced the concept of incommensurability, based on the ‘contextual theory of meaning’ which Feyerabend claimed to find in Wittgenstein's *Investigations*.

1963 ‘How to be a Good Empiricist’, a position paper summing up his point of view, was published, along with his two main articles on the Mind/Body Problem in which he introduced the position now known as ‘eliminative materialism’.

1965 Publication of the first part of the essay ‘Problems of Empiricism’, and his ‘Reply to Criticism’, in which Feyerabend made his last serious attempt to construct a ‘tolerant’, ‘disinfected’ empiricism. Although beginning to put some distance between himself and Popper, Feyerabend was still able to write a glowing review of Popper's *Conjectures and Refutations*.

1967-8 Focus of his published papers had by now moved to ‘theoretical pluralism’, the view that in order to maximise the chances of falsifying existing theories, scientists should construct and defend as many alternative theories as possible. Feyerabend's articles ‘On a Recent Critique of Complementarity’ defended Niels Bohr's views against Popper's critique. Popper not amused.

1969 In a tiny article, ‘Science Without Experience’, Feyerabend finally gave up the attempt to be an empiricist, arguing that in principle experience is necessary at *no* point in the construction, comprehension or testing of empirical scientific theories.

1970 Publication of ‘Consolations for the Specialist’, in which Feyerabend attacked Popper from a Kuhnian point of view, and the essay version of ‘Against Method: Outline of an Anarchistic Theory of Knowledge’, in which ‘epistemological anarchism’ was revealed for the first time. Feyerabend claimed to be applying the liberalism of John Stuart Mill's *On Liberty* to scientific methodology. Published little during the next few years.

1974 Death of Feyerabend's friend Imre Lakatos, putting paid to their plans to produce a dialogue volume, *For and Against Method*. Feyerabend, lecturing at the University of Sussex, was ill too. Published a scathing review of Popper's *Objective Knowledge*.

1975 Appearance of Feyerabend's first book, *Against Method*, setting out ‘epistemological anarchism’, whose main thesis was that there is no such thing as *the* scientific method. Great scientists are methodological opportunists who use any moves that comes to hand, even if they thereby violate canons of empiricist methodology.

1976-7 Feyerabend replies to most of the major reviewers of *Against Method*. Got depressed. Published his first major article on relativism: the first time he explicitly endorsed the view.

1978 *Science in a Free Society* appears, including replies to reviewers of *Against Method*. Some clarification of epistemological anarchism, and very little retreat from the position set out in *AM*. Explored further the political implications of epistemological anarchism. The book also included one of Feyerabend's major endorsements of relativism, one of the views for which he was becoming known. First volume of the German edition of Feyerabend's philosophical papers appears. (Feyerabend published increasingly in German from this point onwards).

1981 English publication of the first two volumes of Feyerabend's *Philosophical Papers*, with new material in introductory chapters.

1983 Met Grazia Borrini at his Berkeley lectures.

1984 Publishes 'Science as an Art', in which he defends an explicitly relativistic account of the history of science according to which there is change, but no 'progress'. Also continues his campaign to rehabilitate Ernst Mach.

1987 Publication of *Farewell to Reason*, a volume collecting some of the papers Feyerabend had published between 1981 and 1987. Relativism again at the forefront, especially in its 'Protagorean' version.

1988 Second, revised edition of *Against Method*, omitting the long chapter on the history of the visual arts, but now incorporating parts of *Science in a Free Society*, appeared.

1989 Paul and Grazia married in January. Left for Italy and Switzerland in the fall, at least partly because of the effects of the October earthquake in California.

1990 Officially resigned from Berkeley in March.

1991 Retired from Zurich. *Three Dialogues on Knowledge* and *Beyond Reason*, a festschrift edited by a former pupil, Gonzalo Munévar, published. Also lots of small publications, many of them in *Common Knowledge*. Signs of an increasing unhappiness with relativism in Feyerabend's publications around this time. But still vigorously opposed to 'objectivism'.

1993 Third edition of *Against Method* published. Feyerabend developed an inoperable brain tumour, and was hospitalized.

1994 Feyerabend died at home in Zurich, February 11th. Several major memorial symposia and colloquia took place over the next two years.

1995 *Killing Time: The Autobiography of Paul Feyerabend* published.

2. Feyerabend's Life and Work: A Critical Appraisal.

(Unless otherwise stated, page references are to *Killing Time: The Autobiography of Paul Feyerabend*, (Chicago: University of Chicago Press, 1995), henceforth referred to as *'KT'*).

Early Life (1924-1938).

Paul Karl Feyerabend was born into a middle-class Viennese family in 1924. Times were hard in Vienna in the nineteen-twenties: in the aftermath of the First World War there were famines, hunger riots, and runaway inflation. Feyerabend's family had a three-room apartment on the *Wolfganggasse*, 'a quiet street lined with oak trees' (p.11). The first chapters of his autobiography give the impression of his being a strange child, whose activities were entirely centred around his own family, and who was cut off from neighbors, other children and the outside world because "[t]he world is a dangerous place" (p.15). Between the ages of three and six, Feyerabend recalls, he spent most of his time in the apartment's kitchen and bedroom. Occasional visits to the cinema and numerous stories, especially stories with a magical aura, seem to have taken the place usually filled by childhood friends. He was a sickly child, but ran away from home once, when he was five years old (p.7). When he started school at the age of six, he

"had no idea how other people lived or what to do with them" (p.16). The world seemed to be filled with strange and inexplicable happenings. It took him some while to get used to school, which initially made him sick. But when he did so, his health problems had disappeared. When he learned to read, he found the new and magical world of books waiting for him, and indulged himself to the full (p.25). But his sense of the world's inexplicability took some time to dissipate - he recalls feeling that way about events during the nineteen-thirties and throughout the second world war.

Feyerabend attended a *Realgymnasium* (High School) at which he was taught Latin, English, and science. He was a *Vorzugsschüler*, that is, ‘a student whose grades exceeded a certain average’ (p.22), and by the time he was sixteen he had the reputation of knowing more about physics and math than his teachers. But he also got thrown out of school on one occasion.

Feyerabend ‘stumbled into drama’ (p.26) by accident, becoming something of a ham actor in the process. This accident then led to another, when he found himself forced to accept philosophy texts among the bundles of books he had bought for the plays and novels they contained. It was, he later claimed, "the dramatic possibilities of reasoning and... the power that arguments seem to exert over people" (p.27) with which philosophy fascinated him. Although his reputation was as a philosopher, he preferred to be thought of as an entertainer. His interests, he said, were always somewhat unfocussed (p.27).

However, Feyerabend's school physics teacher Oswald Thomas inspired in him an interest in physics and astronomy. The first lecture he gave (at school) seems to have been on these subjects (p.28). Together with his father, he built a telescope and ‘became a regular observer for the Swiss Institute of Solar Research’ (p.29). He describes his scientific interests as follows:

> I was interested in both the technical and the more general aspects of physics and astronomy, but I drew no distinction between them. For me, Eddington, Mach (his *Mechanics* and *Theory of Heat*), and Hugo Dingler (*Foundations of Geometry*) were scientists who moved freely from one end of their subject to the other. I read Mach very carefully and made many notes. (p.30).

Feyerabend does not tell us how he became acquainted with another one of his main preoccupations - singing. He was proud of his voice, becoming a member of a choir, and took singing lessons for years, later claiming to have remained in California in order not to have to give up his singing teacher. In his autobiography he talks of the pleasure, greater than any intellectual pleasure, derived from having and using a well-trained singing voice (p.83). During his time in Vienna in the second world war, his interest led him to attend the opera (first the *Volksoper*, and then the *Staatsoper*) together with his mother. A former opera singer, Johann Langer, gave him singing lessons and encouraged him to go to an academy. After passing the entrance examination, Feyerabend did so, becoming a pupil of Adolf Vogel. At this point in his life, he later recalled:

> The course of my life was... clear: theoretical astronomy during the day, preferably in the domain of perturbation theory; then rehearsals, coaching, vocal exercises, opera in the

> evening...; and astronomical observation at night... The only remaining obstacle was the war. (p.35).

The *Anschluss* (1938).

Feyerabend tells how, without falling for Adolf Hitler's charisma, he appreciated Hitler's oratorial style. Austria was re-unified with Germany in 1938. Jewish schoolmates were treated differently, and Jewish neighbours and acquaintances started disappearing. But, as usual, Feyerabend had no clear view of the situation:

> Much of what happened I learned only after the war, from articles, books, and television, and the events I did notice either made no impression at all or affected me in a random way. I remember them and I can describe them, but there was no context to give them meaning and no aim to judge them by. (pp.37-8).

> For me the German occupation and the war that followed were an inconvenience, not a moral problem, and my reactions came from accidental moods and circumstances, not from a well-defined outlook. (p.38).

The general impression given by his autobiography is of an imaginative but fairly solitary person with no stable or well-defined personality. Rather, his decisions and courses of action seem to have been the result of a struggle between his tendency to conform and his contrariness. Just as when he was a child, events happening around him seemed strange, distant, and out of context. It is very difficult to see him identifying with any group, and he must have made an unlikely soldier.

The War (1939-1945).

As far as his army record goes, Feyerabend claims in his autobiography that his mind is a blank. But in fact this is one of the periods he tells us most about. Having passed his final high school exams in March 1942, he was drafted into the *Arbeitsdienst* (the work service introduced by the Nazis), and sent for basic training in Pirmasens, Germany. Feyerabend opted to stay in Germany to keep out of the way of the fighting, but subsequently asked to be sent to where the fighting was, having become bored with cleaning the barracks! He even considered joining the SS, for aesthetic reasons. His unit was then posted Quelerne en Bas, near Brest, in Brittany. Still, the events of the war did not register. In November 1942, he returned home to Vienna, but left before Christmas to join the Wehrmacht's Pioneer Corps.

Their training took place in Krems, near Vienna. Feyerabend soon volunteered for officers' school, not because of an urge for leadership, but out of a wish to survive, his intention being to use officers' school as a way to avoid front-line fighting. The trainees were sent to Yugoslavia. In Vukovar, during July 1943, he learnt of his mother's suicide, but was absolutely unmoved, and obviously shocked his fellow officers by displaying no feeling. In December that same year, Feyerabend's unit was sent into battle on the northern part of the Russian front, but although they blew up buildings, they never encountered any

Russian soldiers.

Despite the fact that Feyerabend reports of himself that he was foolhardy during battle, treating it as a theatrical event, he received the Iron Cross (second class) early in March 1944, for leading his men into a village under enemy fire, and occupying it. He was advanced from private soldier to lance corporal, to sergeant, and then, at the end of 1944, to lieutenant. At the end of November that year, he gave a series of lectures to the officers' school at Dessau Rosslau, near Leipzig. Their theme was the (‘historicist’) one that "historical periods such as the Baroque, the Rococo, the Gothic Age are unified by a concealed essence that only a lonely outsider can understand" (p.49). His description of these lectures, and of his notebook entries at the time, reveals the influence of Friedrich Nietzsche in their fascination with this ‘lonely outsider’, ‘the solitary thinker’ (p.48).

Having returned home for Christmas 1944, Feyerabend again boarded the train for the front, this time for Poland, in January 1945. There he was put in charge of a bicycle company. Although he claims to have relished the role of army officer no more than he later did that of university professor, he must have been at least a competent soldier, since in the field he came to take the place of a sequence of injured officers: first a lieutenant, then a captain, and then a major, before he was shot during another heroic act of carelessness performed in the 1945 retreat westwards from the Russian army. The bullet lodged in his spine left him temporarily paralysed from the waist down, meaning that he spent time in a wheelchair, then on crutches, and thereafter walked with the aid of a stick. The war ended as he was recovering from his injury, in a hospital in Apolda, a little town near Weimar, while fervently hoping not to recover before the war was over. Germany's surrender came as a relief, but also as a disappointment relative to past hopes and aspirations. He later said of his stint in the army that it was "an interruption, a nuisance; I forgot about it the moment it was over" (p.111).

Post-War Activities (1945-1947).

However, the war took its toll even on Feyerabend. The bullet in his spine left him impotent for the rest of his life. (His descriptions of subsequent sexual encounters are one of the more amusing parts of his autobiography). Although he started off completely ignorant of women, he married four times, and had, by his own account, plenty of affairs. But he seems to have been distant not just in his relationship with his parents, but in some of his marriages too. He hated the slavery love seemed to imply, but hated equally the freedom achieved by taking evasive action. He got bogged down in cycles of dependence, isolation, and renewed dependence, which only dissolved into a more balanced pattern after many years.

At the end of the war, Feyerabend went to the mayor of Apolda and asked for a job. He was assigned to the education section, given an office and a secretary and, fittingly, put in charge of entertainment.

In 1946, having recovered from paralysis, he received a state fellowship to return to study singing and stage-management for a year at the *Musikhochschule* in Weimar. He moved from Apolda to Weimar after about three months. At the Weimar *Institut zur Methodologischen Erneuerung des Deutschen Theaters* he studied theatre, and at the Weimar academy he took classes in Italian, harmony, piano,

singing and enunciation. Singing remained one of his life's major interests. He attended performances (drama, opera, ballet, concerts) at Weimar's *Nationaltheater*, and later reminisced about opera stars of the time, recalling debates and arguments about theatre (e.g. the stereotyping of roles and plays) with Maxim Vallentin, Hans Eisler, etc. He also played a small part in one of the films of G.W.Pabst, a notable German film-director. Although, by his own account, he led a full life, he became restless and decided to move.

Return to Vienna: University Life, Alpbach, and Popper (1947-1948).

Feyerabend therefore returned, still on crutches, to his parents' apartment house in Vienna's 15th district. Although he planned to study physics, maths and astronomy, he chose instead to read history and sociology at the University of Vienna's *Institut für Osterreichische Geschichtsforschung*, thinking that history, unlike physics, is concerned with real life. But he became dissatisfied with history, and returned to theoretical physics. Together with a group of science students, who all regarded themselves as far superior to students of other subjects, Feyerabend invaded philosophy lectures and seminars. Although this was not his first contact with philosophy, it seems to have been the period which cemented his interest. He recalls that in all interventions he took the radical positivist line that science is the basis of knowledge; that it is empirical; and that nonempirical enterprises are either logic or nonsense (p.68). These views would have been familiar from the climate of Logical Positivism which found its main root in the Vienna Circle, a group of scientifically-minded philosophers who, in the nineteen-twenties and 'thirties sought to deploy the newly-revitalised formal logic of Gottlob Frege and Russell and Whitehead's *Principia Mathematica* to represent the structure of human knowledge. As we shall see, Feyerabend's youthful positivist scientism makes quite a contrast with his later conclusions.

In August 1948, at the first meeting of the international summer seminar of the Austrian College Society in Alpbach which he attended, Feyerabend met the philosopher of science Karl Popper, who had already made a name for himself as the Vienna Circle's 'official opposition'. (The Austrian College Society had been founded in 1945 by Austrian resistance fighters, 'to provide a forum for the exchange of scholars and ideas and so to prepare the political unification of Europe' (*Science in a Free Society*, p.109)). In his 1934 book *Logik der Forschung* Popper had elaborated the straightforward and appealing falsificationist view that great science could be characterised as a process in which thinkers put forward bold conjectures and then do their best to improve them by trying to refute them. Instead of trying to develop an inductive logic, Popper argued for the (deductivist) view that scientific method could be characterised in terms of logically valid deductive inferences.

Popper's own autobiography, unfortunately, tells us nothing about their meeting or their relationship, despite the fact that he was to be the largest single influence (first positive, then negative) on Feyerabend's work. For those hoping that Feyerabend might use the occasion of his autobiography to settle accounts with his erstwhile philosophical conscience, it is disappointing that the book tells us so little about his acquaintance with Popper. Elsewhere Feyerabend tells us that he

> admired [Popper's] freedom of manners, his cheek, his disrespectful attitude towards the

> German philosophers who gave the proceedings weight in more senses than one, his sense of humour... [and] his ability to restate ponderous problems in simple and journalistic language. Here was a free mind, joyfully putting forth his ideas, unconcerned about the reaction of the 'professionals'. (*SFS*, p.115).

But Popper's ideas themselves, Feyerabend alleges, were not new to him, deductivism having been defended as early as 1925 by Viktor Kraft, and falsificationism being 'taken for granted' at Alpbach. Popper's ideas, he remarks, were also similar to those of another Viennese philosopher, Ludwig Wittgenstein (!), although 'more abstract and anaemic' (*SFS*, p.116). Over the following years, Feyerabend attended the Alpbach symposium about fifteen times, first as a student, then as a lecturer and seminar chair. He was offered, and accepted, the post of 'scientific secretary' to the society, and this he calls 'the most decisive step of my life' (p.70). In fact, it is this decision which answers his self-addressed questions about the origin of his career, his reputation, and his situation at the time of writing his autobiography, since he traces his situation back to it.

At Alpbach he was also approached by communists, including the Marxist intellectual Walter Hollitscher, who became his teacher and friend. Feyerabend resisted Hollitscher's political arguments on the basis of his own 'youthful elitism' and 'an almost instinctive aversion to group thinking' (p.73). But although Feyerabend later described himself as having been 'a raving positivist' at the time, it was Hollitscher, he says, who persuaded him of the cogency of realism about the 'external world' (Popper's important arguments for realism came somewhat later). The considerations Hollitscher deployed were, first, that scientific research was conducted on the assumption of realism, and could not be otherwise conducted, and, second, that realism is fruitful and productive of scientific progress, whereas positivism was simply a commentary on scientific results, barren in itself.

> Hollitscher never presented an argument that would lead, step by step, from positivism to realism and he would have regarded the attempt to produce such an argument as philosophical folly. He rather developed the realist position itself, illustrated it by examples from science and commonsense, showed how closely it was connected with scientific research and everyday action and so revealed its strength. (*SFS*, p.113).

Feyerabend eventually developed these thoughts in a fascinating series of papers beginning in 1957, arguing that science needs realism in order to progress, and that positivism would stultify such progress. The argument was entirely in line with Popper's approach, as well as with his conclusions.

Early Contact with Wittgenstein (1948-1952).

Feyerabend's principal intellectual engagement in the late 1940s and early 1950s was in his capacity as student leader of the 'Kraft Circle'. Viktor Kraft was a former member of the Vienna Circle, and became Feyerabend's dissertation supervisor. The Kraft Circle was a philosophy club centred around Kraft, which constituted another part of the Austrian College Society. Bela Juhos, Walter Hollitscher, Georg Henrik von Wright, Elizabeth Anscombe and Wittgenstein were all visiting speakers. Feyerabend reports

that the Circle held meetings from 1949 to 1952 or ‘53 (*SFS*, p.109), that they set themselves the task of ‘considering philosophical problems in a nonmetaphysical manner and with special reference to the findings of the sciences’ (‘Herbert Feigl: A Biographical Sketch’, in P.K.Feyerabend & G.Maxwell (eds.), *Mind, Matter, and Method: Essays in Philosophy and Science in Honor of Herbert Feigl*, (Minneapolis: University of Minnesota Press, 1966), pp.1-2) and that their main topics of discussion were the questions of the reality of theoretical entities and of the ‘external world’. About Wittgenstein's lecture, Feyerabend recalls the following:

> Not even a brief and quite interesting visit by Wittgenstein himself (in 1952) could advance our discussion. Wittgenstein was very impressive in his way of presenting concrete cases, such as amoebas under a microscope... but when he left we still did not know whether or not there was an external world, or, if there was one, what the arguments were in favour of it. (Feyerabend & Maxwell ibid., p.4. Note that Feyerabend must have got the date wrong, since Wittgenstein died in April 1951).
>
> Wittgenstein, who took a long time to make up his mind and then appeared over an hour late gave a spirited performance and seemed to prefer our disrespectful attitude to the fawning admiration he encountered elsewhere. (*SFS*, p.109).

In 1949, Feyerabend was introduced to Bertholt Brecht, and Hollitscher offered him the opportunity to become one of Brecht's production assistants, but he turned it down, later describing this as one of the biggest mistakes of his life (*SFS*, p.114). In the autobiography, however, he retracts this statement, saying that he would not have enjoyed being part of the closely knit group that surrounded Brecht. (The reasons for his later defection from the Popperian camp seem to have been similar).

The University of Vienna's physicists were Hans Thirring, Karl Przibram, and Felix Ehrenhaft. Feyerabend admired Thirring and Ehrenhaft, and was influenced by Ehrenhaft, who had lectured on physics there from 1947. Ehrenhaft was known as a fierce and independent critic of all kinds of orthodoxy in physics, but was sometimes thought of as a charlatan. Feyerabend reports that he and his fellow science students looked forward to exposing him as a fraud, but in fact were treated, at the 1949 Alpbach seminar, to a battle between Ehrenhaft and the orthodox in which the former presented his experiments but the latter defended their position by using strategies which Galileo's opponents would have been proud of, ridiculing Ehrenhaft's phenomena as mere *Dreckeffects*. Feyerabend commented that "Only much later did Ehrenhaft's lesson sink in and our attitude at the time as well as the attitude of the entire profession provided me then with an excellent illustration of the nature of scientific rationality" (*SFS*, p.111). Ehrenhaft did not convince the theoreticians, who protected themselves with an iron curtain of dogmatic belief of exactly the same kind as that deployed by Galileo's opponents. His audience remained staunch empiricists, never doubting that science had to be adapted to facts. Feyerabend commented that the day-to-day business of science, what Thomas Kuhn called ‘normal science’, cannot exist without this kind of ‘split consciousness’.

At the University of Vienna, although he had originally planned to submit a thesis on physics,

Feyerabend swapped to philosophy when he got nowhere with the electrodynamics problem he was calculating (the philosopher of science as failed scientist?). He completed his doctoral thesis, '*Zur Theorie der Basissätze*' in 1951 under Kraft's supervision. The subject of the thesis was 'basic sentences', or 'protocol sentences', i.e. the kind of sentences that, the Logical Positivists had theorised, comprise the foundations of scientific knowledge. He later reported that in his philosophical work he had "started from and returned to the discussion of protocol statements in the Vienna Circle" ('Concluding Unphilosophical Conversation', in Munévar (1991), p.526). This is unsurprising, given that Kraft was then the Vienna Circle's only survivor in Vienna. However, Kraft's influence on Feyerabend has only recently been emphasised. Much of the material from Feyerabend's thesis was presented at (or gleaned from) meetings of the Kraft Circle, and also appears in his early articles, such as 'An Attempt at a Realistic Interpretation of Experience' (1958). The thesis itself was 'a condensed version of the discussions in the Kraft Circle' (p.115).

In the early 1950's, Feyerabend published several German papers on Wittgenstein, written as a result of having read the proofs of the *Philosophical Investigations*, lent to him by Elizabeth Anscombe. Feyerabend first met Anscombe when lecturing on Descartes to the Austrian College Society. Anscombe had come to Vienna to perfect her German in order to translate Wittgenstein's works.

> She gave me manuscripts of Wittgenstein's later writings and discussed them with me. The discussions extended over months and occasionally proceeded from morning over lunch until late into the evening. They had a profound influence upon me though it is not at all easy to specify particulars. (*SFS*, p.114).

Feyerabend planned to study with Wittgenstein in Cambridge, and Wittgenstein was prepared to take him on as a student, but he died before Feyerabend arrived in England. Karl Popper became his supervisor instead.

Life at the London School of Economics (1952-1953).

In Feyerabend's autobiography, we are told a little about Popper's lectures and his famous LSE seminar. The lectures began with the claim that there is no method in science, but that there *are* some simple and helpful rules of thumb. Popper tried to show "how simple ideas that were derived from equally simple requirements brought order into the complex world of research" (pp.88-9). Having being convinced by Popper's and Pierre Duhem's critiques of inductivism (the view that science proceeds through generalisation from facts recorded in experience), Feyerabend considered falsificationism a real option, and, he says, "fell for it" (p.89), applying falsificationism in his papers and lectures. This is not his first admission that he was a falsificationist, but it is notable that he did not see it as entailing his having been a Popperian. Feyerabend was (usually) a fairly *liberal* falsificationist, always emphasising the tenacity with which scientists should defend their theories, and allowing that scientific theories can start by being untestable. Faithful Popperians like John Watkins and Joseph Agassi, he emphasises, continually ticked him off for being unorthodox (he was later accused, by Agassi, of plagiarising from Popper). Instead he later saw this interlude as an example of the dangers of abstract reasoning. Rationalism is already

dangerous, since it ‘paralyses our judgment’ (p.89) and is invested with ‘an almost superhuman authority’ (p.90). But Popper added a further dangerous element: *simplicity*. Such a philosophy, complains Feyerabend, "may be out of touch with reality... [that is], with scientific practice" (p.90).

Feyerabend is here referring to Popper's approach to the epistemology of science, which he himself followed and furthered for quite a while. In chapter II of *The Logic of Scientific Discovery* (1934), Popper had distinguished between scientific practice and scientific standards, principles, or methodology. Arguing against a ‘naturalistic’ theory of method which makes standards depend on practice, Popper opted instead for a strongly normative epistemology, a discipline which lays down optimum rules of method for scientists to follow. This is one of the most important aspects of the Popperian perspective which Feyerabend originally took on board.

Such an epistemology, Feyerabend now complains, makes the false assumption that ‘rational’ standards can lead to a practice that is as mobile, rich and effective as the science we already have. Falsificationism would destroy science as we know it. Science did not develop in accordance with Popper's model. It is not ‘irrational’, but it contains no overarching pattern. Popper's rules could produce a science, but not the science we now have. (Feyerabend remarks that the Logical Positivist Otto Neurath had already put this criticism of Popper some time before (p.91)).

In 1952, Feyerabend presented his ideas on scientific change to Popper's LSE seminar and to a gathering of illustrious Wittgensteinians (Elizabeth Anscombe, Peter Geach, H.L.A.Hart and Georg Henrik von Wright) in Anscombe's Oxford flat. This meeting seems to have been the first airing of the important concept of *incommensurability* (although not the term itself, which crept into publications only a decade later):

> On one occasion which I remember vividly Anscombe, by a series of skilful questions, made me see how our conception (and even our perceptions) of well- defined and apparently self-contained facts may depend on circumstances not apparent in them. There are entities such as physical objects which obey a ‘conservation principle’ in the sense that they retain their identity through a variety of manifestations and even when they are not present at all while other entities such as pains and after-images are ‘annihilated’ with their disappearance. The conservation principles may change from one developmental stage of the human organism to another and they may be different for different languages (cf. Whorf's ‘covert classifications’...). I conjectured that such principles would play an important role in science, that they might change during revolutions and that deductive relations between pre-revolutionary and post-revolutionary theories might be broken off as a result. (*SFS*, p.115).
>
> Major discoveries, I said, are not like the discovery of America, where the general nature of the discovered object is already known. Rather, they are like recognizing that one has been dreaming. (*KT*, p.92).

These thoughts received an unenthusiastic reception from Hart, von Wright and Popper.

Feyerabend's articles on Wittgenstein culminated in his review of the *Philosophical Investigations*, the text of which he studied in detail while he was in London. (‘Being of a pedantic turn of mind’, he says, ‘I rewrote the book so that it looked more like a treatise with a continuous argument’. (*SFS*, p.116)). Anscombe translated Feyerabend's summary into English and sent it to *The Philosophical Review*. It was accepted by the editor, Norman Malcolm (having been turned down by Gilbert Ryle, editor of *Mind* - see *KT*, p.93). This review was Feyerabend's first English-language publication; he called it his ‘Wittgensteinian monster’ (p.115). He later commented:

> I knew that Wittgenstein did not want to present a theory (of knowledge, or language), and I did not expressly formulate a theory myself. But my arrangements made the text speak like a theory and falsified Wittgenstein's intentions. (*KT*, p.93).
>
> Wittgenstein's emphasis on the need for concrete research and his objections to abstract reasoning (‘Look, don't think!) somewhat clashed with my own inclinations and the papers in which his influence is noticeable are therefore mixtures of concrete examples and sweeping principles. (*SFS*, p.115).

In his review of the *Philosophical Investigations*, he summarised the book in a very effective way, drawing particular attention to Wittgenstein's critique of a family of ‘realist’ or ‘essentialist’ theories of meaning according to which the meaning of a word is the object designated or referred to by that word. Feyerabend argued that Wittgenstein was attempting a *reductio ad absurdum* of realist theories, showing that they had the untenable implication that we could not be said to know the meaning of words which we nevertheless constantly use in totally unproblematic ways.

Unfortunately, as I have argued at length elsewhere, (Preston 1997, ch.2), Feyerabend completely failed to follow up this insight by endorsing Wittgenstein's non-representationalist conception of meaning, according to which the meaning of a term is determined by its *use*. Instead, wrongly associating the idea that meaning is use with positivism, Feyerabend proferred what he called a ‘contextual’ theory of meaning, which identified the meaning of a term or statement with whatever role it plays in *theoretical* contexts. But he over-extended the idea of the theoretical to cover *any* context whatever, thus completely depriving it of content. For Feyerabend, the theoretical contrasts with nothing at all.

The book review was also critical of Wittgenstein, though. Notably, it railed against Wittgenstein's conception of philosophy (as ‘philosophical analysis’). In a short article published the next year (1956), Feyerabend expanded on his critique, arguing that consideration of G.E.Moore's famous ‘paradox of analysis’ showed that "*philosophy cannot be analytic and scientific*, i.e., interesting, progressive, about a certain subject matter, informative *at the same time*" (‘A Note on the Paradox of Analysis’, p.95). Feyerabend thenceforth plumped for (what he conceived of as) *scientific* philosophy. Like Popper, he had very little time for the kind of ‘analytic’ philosophy or ‘linguistic’ philosophy which followed in Wittgenstein's wake, and with which Oxford University dominated the philosophical scene in the 1950s

and early 1960s.

One of the things that comes across most clearly from his autobiography is the consistently malleable nature of Feyerabend's views. He records that his friend Agassi caused him completely to change his mind about a book he considered translating. When Agassi urged Feyerabend to become a faithful Popperian, Feyerabend's resistance seems to have been based mainly on his aversion to groups.

Return to Vienna (1953-1955).

By the summer of 1953, when Popper had to apply for extra funds to allow Feyerabend to work as his assistant, Feyerabend had decided to leave the Popperian church and return to Vienna. Although the assistantship was soon approved, Feyerabend ‘felt quite uncomfortable. I couldn't put my finger on it; I only knew that I wanted to remain in Vienna’ (p.99).

During this period Feyerabend, having nothing to do and needing the money, translated Popper's ‘war effort’, *The Open Society and its Enemies* into German, wrote articles on ‘Methodology’ and ‘Philosophy of Nature’ for a French encyclopaedia, produced a report on post-war developments in the Humanities in Austria for the U.S. Library of Congress, and made a mess of his first professional opportunity as a singer (p.98). But he also felt that he did not know what to do in the long run, so he applied for jobs in various universities.

He then met Arthur Pap, ‘who had come to Vienna to lecture on analytic philosophy and who hoped, perhaps somewhat unrealistically, that he would be able to revive what was left from the great years of the Vienna Circle and the analytic tradition there’ (‘Herbert Feigl: A Biographical Sketch’, p.3). Feyerabend became Pap's assistant. Pap arranged for him to meet Herbert Feigl in Vienna in 1954, and together they studied Feigl's papers. Feigl had been a member of the Vienna Circle until his emigration to the USA in 1930, but he had never given up the ‘realist’ view that there is a knowable external world. He convinced Feyerabend that the positivism of Kraft and Pap had not solved the traditional problems of philosophy. His paper ‘Existential Hypotheses’ (1950), together with Kraft's contributions and certain ideas Popper had put forward at Alpbach in 1948 and 1949, greatly diminished Feyerabend's doubts about realism (ibid., p.4). Here is how Feyerabend recounts Feigl's influence:

> It was ... quite a shock to hear Feigl expound fundamental difficulties and to hear him explain in perfectly simple language without any recourse to formalism why the problem of application [of the probability-calculus] was still without a solution. Formalization, then, was not the last word in philosophical matters. There was still room for fundamental discussion-for speculation (dreaded word!); there was still a possibility of overthrowing highly formalized systems with the help of a little common sense! (ibid., p.5).

1954 saw the publication of the first of Feyerabend's many articles on the philosophy of quantum mechanics, the first fruits of the time he spent studying with Popper. In these publications, he generally took the line that the dominance achieved by the ‘Copenhagen Interpretation’ of the quantum theory was

undeserved. Feyerabend was particularly keen to argue that it had not and could not be shown that this interpretation of the theory was a general panacea for the problems of microphysics, or that its defenders could justifiably believe it to be unassailable. He came to defend the right of ‘hidden-variables’ theorists such as Louis de Broglie, David Bohm, and Jean-Pierre Vigier to hypothesise the existence of an unobserved deterministic substructure underpinning the apparently indeterministic cavortings of objects on the quantum-mechanical level.

However, Feyerabend also came to think that Popper's earlier critique of the Copenhagen orthodoxy had been somewhat limited and superficial. According to Popper, the Copenhagen Interpretation was simply the result of some bad positivistic philosophising. Niels Bohr and Werner Heisenberg, on this view, had been seduced by positivist philosophers (like Ernst Mach and his ostensible followers, the Vienna Circle) into thinking that their theory was not conjectural but was merely a compendious, economical but non-hypothetical *description* of experience. Feyerabend argued that, on the contrary, the Copenhagen theorists had some perfectly good ‘physical’, ‘scientific’, or ‘factual’ arguments for thinking that their view alone was currently compatible with the observed results of experiments. He therefore put forward a *defence* of their instrumentalist interpretation of the quantum theory. But the defence was only tactical, since he ultimately argued that the observed results of experiments themselves needed to be *challenged* by a point of view which would reveal their truth or falsity. So Feyerabend used the quantum case to push for a reconsideration of the methodological rules to which scientists subscribe. This is the genesis of his idea of a ‘pluralistic’ test model, in which theories are compared with one another, as well as against ‘experience’. (Note, however, that this idea can already be found in Popper, and that Feyerabend did initially acknowledge this fact). According to Feyerabend, only by endorsing scientific realism can the scientist cleave to a methodology which would consistently bring out the (conceptually) *revolutionary* potential of scientific theories, rekindling the kind of fire Galileo had lit under the Aristotelian world-view. Such a realism interprets theories *not* as summaries of experience, but as genuine conjectures about a mind-independent reality. It also puts the observation-language of science in the same epistemological boat as its theoretical terms: observations, he urged, are just as ‘theoretical’ (that is, hypothetical) as theories: "Logically speaking, all terms are ‘theoretical’" (*Philosophical Papers, Volume 1*, p.32 note).

First Academic Appointment: the University of Bristol (1955-1958).

In 1955, with the help of references from Popper and Erwin Schrödinger, as well as his own big mouth (*SFS*, p.116, *KT*, p.102), Feyerabend secured his first academic post lecturing in philosophy of science at the University of Bristol, England. In his autobiography (pp.103-4) he describes how Agassi had to help him prepare for these lectures, since they covered a subject Feyerabend had never studied (see also *SFS*, p.116). He also describes how for some time he felt directionless and unsettled: he was ‘killing time’.

In the summer of that year, he again visited Alpbach, where he met the philosopher of science Philipp Frank (another former Logical Positivist), who exerted on him a (somewhat delayed) influence:

> Frank argued that the Aristotelian objections against Copernicus agreed with empiricism, while Galileo's law of inertia did not. As in other cases, this remark lay dormant in my

> mind for years; then it started festering. The Galileo chapters of *Against Method* are a late result. (*KT*, p.103. See also *SFS*, p.112).

Around the same time, Feyerabend met David Bohm, who was lecturing in physics at the University of Bristol. Bohm had been the favoured protegé of Niels Bohr, and his first book (*Quantum Theory*, (Englewood Cliffs, NJ: Prentice-Hall, 1951))was a lengthy defence of the Copenhagen Interpretation of the quantum theory. But in the early 1950s Bohm rejected his former view, and became one of the leading defenders of the then-unpopular ‘hidden-variables’ theory. He was to be a significant influence on Feyerabend, weaning him away from Popper with his somewhat Hegelian account of the structure of reality. In their later work, Bohm and Feyerabend moved in parallel directions, towards an interest in ‘fringe’ science. Feyerabend produced a critical study of Bohm's 1957 book *Causality and Chance in Modern Physics* in 1960, when he was still very much under Popper's influence. But, as always with Feyerabend, Bohm's ideas sunk in gradually, and had visible effect only in his productions of the early 1970s.

In 1956, Feyerabend got married for the second time, this time to one of his former students, Mary O'Neill. But this relationship seems to have been very short-lived, for he reports that his wife spent Christmas 1957 away from him with her parents, that she subsequently had an affair, and that the last time he saw her was 1958.

Feyerabend remembers his Bristol lecture course on quantum mechanics as being a disaster. However, in the summer of 1956, along with Alfred Landé, he chaired a successful seminar on philosophical issues in quantum mechanics at Alpbach. A related success was his contribution to the 1957 Colston Research Symposium, where he gave a paper ‘On the Quantum Theory of Measurement’. Here Feyerabend introduced what was to become a long-running theme in his work: that there is no separate and neutral ‘observation-language’ or ‘everyday language’ against which the theoretical statements of science are tested, but that ‘the everyday level is *part of* the theoretical rather then something self-contained and independent’ (*Philosophical Papers, Volume I*, p.217, emphasis added). This was his principal contribution to his central subject, the relation between theory and experience. It constituted not only a decisive break with the positivist conception of theories, but also something of a step beyond Popper's conception.

The University of California at Berkeley: Early Years (1958-1964).

In the summer of 1957, Feyerabend accepted an invitation from Michael Scriven to visit the Minnesota Center for the Philosophy of Science in Minneapolis. The Center was, as Feyerabend later said, ‘one of the foremost institutions in the field’ (p.115). There he met Feigl, Carl Hempel, Ernest Nagel, Hilary Putnam, Adolf Grünbaum, Grover Maxwell, E.L.Hill, Paul Meehl, and others. He returned to the Center in 1958, having accepted another invitation to work there, backed by an NSF grant. He often went back there in subsequent years.

Around this time, many of Feyerabend's most important early papers were published. In them, under the

influence of both Popper and Wittgenstein, Feyerabend initiated a vigourous critique of the then-orthodox philosophies of science provided by descendants of the Vienna Circle, ‘Logical Empiricist’ thinkers such as Rudolph Carnap, Feigl, Nagel, and Hempel. This critique was conducted through a study of the relationship between observation and theory.

In perhaps the most important of these early publications, ‘An Attempt at a Realistic Interpretation of Experience’ (1958), Feyerabend argued against positivism and in favour of a scientific realist account of the relation between theory and experience, largely on grounds familiar from Karl Popper's falsificationist views. Positivist theories of meaning, he complained, have consequences which are ‘at variance with scientific method and reasonable philosophy’ (*Philosophical Papers, Volume 1*, p.17). In particular, they imply what Feyerabend dubbed the ‘stability thesis’, that even major changes in theory will not affect the meanings of terms in the scientific observation-language. Against this supposition, Feyerabend defended what he called ‘Thesis I’, the idea that

> *the interpretation of an observation-language is determined by the theories which we use to explain what we observe, and it changes as soon as those theories change*. (ibid., p.31).

Thesis I reversed the direction of interpretation which the positivists had presupposed. Instead of meaning seeping upwards from the level of experience (or the observation-language), Feyerabend had it trickling down *from* theory *to* experience. For him, theory is meaningful independently of experience, rather than vice-versa. The roots of this view clearly lie in his contextual theory of meaning, according to which meaning is conferred on terms by virtue of their participation in *theoretical* contexts. It seems to imply that there is no principled semantic distinction between theoretical terms and observation terms. And Feyerabend soon followed up this implication with his ‘Pragmatic Theory of Observation’, according to which what is important about observation-sentences is not their having a special core of empirical meaning, but their causal role in the production and refutation of theories.

In 1958, Feyerabend had been invited to spend one year at the University of California at Berkeley, and accepted. When this visiting appointment ended, the University administration decided to hire him on the basis of his publications and, of course, his big mouth (p.115). But because of his grant to work at Minneapolis, he only started lecturing full-time at Berkeley in 1960. There he encountered Thomas Kuhn, and read Kuhn's forthcoming book *The Structure of Scientific Revolutions* in draft form. He then wrote to Kuhn about the book (these letters have recently been published in *Studies in the History and Philosophy of Science*, **26**, 1995). But he was not quite ready to take on Kuhn's descriptive-historical approach to the philosophy of science. Although more and more historical examples peppered his published work, he was still using them to support fairly orthodox falsificationist conclusions.

In his meta-methodology, Feyerabend applied to the dispute over the interpretation of scientific theories a strong measure of Popperian methodological conventionalism, arguing that the dispute between realists and instrumentalists is not a factual issue but a matter of choice. We can choose to see theories either as descriptions of reality (scientific realism) or as instruments of prediction (instrumentalism), depending on what ideals of scientific knowledge we aspire to. Adherence to these competing ideals (roughly: high

informative content on the one hand, and sense-certainty on the other) is to be judged by their respective consequences. Stressing that philosophical theories have not merely reflected science but have *changed* it, Feyerabend argued further that the *form* of our knowledge can be altered to fit our ideals. So we can *have* certainty, and theories that merely summarise experience, if we wish. But, mobilising the usual equation between empirical content and testability (common to Carnap, Popper and Feyerabend), he urged that we should decisively reject the ideal of certainty and opt instead for theories which go beyond experience and say something informative about reality itself. In this respect, he clearly followed Popper's lead, reconstruing empiricism as a doctrine about the most desirable form for our theories, rather than as a view about the sources of knowledge.

Feyerabend argued that the idea, common to positivists, that the interpretation of observation terms doesn't depend upon the status of our theoretical knowledge, has consequences undesirable to positivists. One of these is that "every positivistic observation language is based upon a metaphysical ontology" (*Philosophical Papers, Volume 1*, p.21). Another follows from the thesis, which he relishes, that the theories we hold influence our language, and maybe even our perceptions. This implies that as long as we use only one empirically adequate theory, we will be unable to imagine alternative accounts of reality. If we also accept the positivist view that our theories are summaries of experience, those theories will be void of empirical content and untestable, and hence there will be a diminution in the critical, argumentative function of our language. Just as purely transcendent metaphysical theories are unfalsifiable, so too what began as an all-embracing scientific theory offering certainty will, under these circumstances, have become an irrefutable dogma, a *myth*. Elsewhere (Preston 1997, chapter 5) I have argued that his antipathy toward this ‘myth predicament’ was one the main driving-forces behind Feyerabend's views at the time.

Feyerabend defended a realism according to which "the interpretation of a scientific theory depends upon nothing but the state of affairs it describes" (*Philosophical Papers, Volume 1*, p.42). At the same time he claimed to find in Wittgenstein's *Philosophical Investigations* a contextual theory of meaning according to which the meaning of terms is determined not by their use, nor by their connection with experience, but by the role they play in the wider context of a theory or explanation. Thesis I, the key proposition of Feyerabend's early work, is supposed to encapsulate *both* the contextual theory of meaning and scientific realism. Only realism, by insisting on interpreting theories in their most vulnerable form as universally-quantified statements which strive for truth, leads to scientific progress instead of stagnation, he argued. Only realism allows us to live up to the highest intellectual ideals of critical attitude, honesty, and testability.

Unlike positivism, which conflicts with science by taking experiences as unanalysable building-blocks, realism treats experiences as analysable, explaining them as the result of processes not immediately accessible to observation. Experiences and observation-statements are thus revealed as more complex and structured than positivism had realised. Feyerabend over-extended the contextual theory of meaning to apply not only to theoretical terms but to observation terms too, arguing that there is no special ‘problem’ of theoretical entities, and that the distinction between observation terms and theoretical terms is a purely pragmatic one. If, as the contextual theory also implies, observation-statements depend on theoretical principles, any inadequacy in these principles will be transmitted to the observation-

statements they subtend, whence our beliefs about what is observed may be in error, and even our experiences themselves can be criticised for giving only an approximate account of what is going on in reality. *All* our statements, beliefs and experiences are ‘hypothetical’. Observations and experiments always need interpretation, and different interpretations are supplied by different theories. If existing meanings embody theoretical principles, then instead of passively accepting observation- statements, we should attempt to find and test the theoretical principles implicit in them, which may require us to change those meanings.

Feyerabend therefore idolised semantic instability, arguing that the semantic stability presupposed by positivist accounts of reduction, explanation and confirmation, has been and should be violated if we want progress in science. If meaning is determined by theory, terms in very different theories simply cannot share the same meaning: they will be ‘incommensurable’. Any attempt to derive the principles of an old theory from those of a new one must either be unsuccessful or must effect a change in the meaning of the old theory's terms. The ‘theoretical reduction’ beloved of Logical Empiricists is therefore actually more like *replacement* of one theory and its ontology by another. At the end of his well-known 1962 paper ‘Explanation, Reduction, and Empiricism’, in which he introduced the concept of incommensurability, Feyerabend concluded that this concept precluded any formal account of explanation, reduction or confirmation. (Kuhn's book *The Structure of Scientific Revolutions*, in which the same term was used to characterize a related concept, was published in the same year).

In his first major published excursion from the philosophy of science, Feyerabend applied these ideas to the mind/body problem. In two papers published in 1963, he sought to defend materialism (roughly, the view that everything which exists is physical) against the supposition that the mind cannot be a physical thing. Although these papers exhibit a rather unclear mixture of views, they are now remembered primarily for having ushered in the position known as *‘eliminative materialism’*, according to which our way of conceiving the mind and mental phenomena amounts to a seriously inadequate theory which is in conflict with a (materialistic) scientific account of those same things. Feyerabend suggested that the two theories in question were incommensurable, but that nevertheless we ought to prefer the materialistic one on general methodological grounds. This radical view of the mind/body problem has been one of Feyerabend's most important legacies. Even though Feyerabend himself seems to have given it up in the late 1970s, it was taken up by Richard Rorty and, more recently, by Paul and Patricia Churchland.

In Feyerabend's version of the incommensurability thesis, the semantic principles of construction underpinning a theory (in its *realist* interpretation) can be violated or ‘suspended’ by another theory. As a result, theories cannot always be compared with respect to their content, as ‘rationalists’ would like. It took Feyerabend a while to see it, for he did *not* officially subscibe to this view until the late 1960s, but this opens the door to relativism, the view that there is no objective way of choosing between theories or traditions. This is perhaps the most notorious and widely-reviled consequence of the contextual theory of meaning.

In the ground-breaking central papers from this period of Feyerabend's oeuvre such as ‘How to be a Good Empiricist’ (1963), ‘Realism and Instrumentalism’ (1964), ‘Problems of Empiricism’ and ‘Reply to Criticism’ (1965), his most important argument for scientific realism was methodological: realism is

desirable because it demands the proliferation of new and incompatible theories. This leads to scientific progress because it results in each theory having more empirical content that it otherwise would, since a theory's testability is proportional to the number of potential falsifiers it has, and the production of alternative theories is the only reliable way to ensure the existence of potential falsifiers. So scientific progress comes through *‘theoretical pluralism’*, allowing a plurality of incompatible theories, each of which will contribute by competition to maintaining and enhancing the testability, and thus the empirical content, of the others. According to Feyerabend's *pluralistic test model*, theories are tested against one another. He thus idealised what Kuhn called ‘pre-paradigm’ periods and ‘scientific revolutions’, occasions when there are many incompatible theories, all forced to develop through their competition with each other. But he downplayed the idea that theories are still compared with one another primarily for their ability to account for the results of observation and experiment. For Feyerabend, this idea was an empiricist myth which disguised the role of aesthetic and social factors in theory-choice.

Thus far, the argument for theoretical pluralism largely follows that of John Stuart Mill's *On Liberty* (1859), to which Feyerabend often paid homage. But Feyerabend went on to try to demonstrate a mechanism whereby theories can augment their empirical content. According to this part of the argument, theories may face difficulties which can only be discovered with the help of alternative theories. A theory can be incorrect without our being able to discover this in a direct way: sometimes the construction of new experimental methods and instruments which would reveal the incorrectness is excluded by laws of nature, sometimes the discrepancy (were it to be discovered) might be regarded as an oddity, and might never be given its correct interpretation. Circumstances can thus conspire to hide from us the infirmities of our theory. The methodological ‘principle of testability’ demands that we develop alternative theories incompatible with the existing theory, and develop them in their strongest form, as descriptions of reality, not mere instruments of prediction. Instead of waiting until the current theory gets into difficulties, and only then starting to look for alternatives, we ought vigorously to proliferate theories and tenaciously defend them in the hope that they may afford us an *indirect refutation* of our existing theory. Only theories which are empirically adequate will thus contribute to raising the empirical content of their fellows. But Feyerabend insists that *any* theory, no matter how weak, may *become* empirically adequate, and so may contribute to this process. To be a realist, he therefore suggests, involves demanding support for any theory, including implausible conjectures having no independent empirical support, conjectures which are inconsistent with data and well-confirmed laws. We should retain theories that are in trouble, and invent and develop theories that contradict the observed phenomena, just because in doing so we will be respecting the intellectual ideal of testability.

In thus appealing to the ‘principle of testability’ as the supreme methodological maxim, Feyerabend forgets that testability must be traded-off against other theoretical virtues. Only his pathological fear of theories losing their empirical content and becoming myths leads him to want to maximise testability and embrace an absolutely unrestricted principle of proliferation. He also disregards historical evidence that anti-realist approaches can be just as pluralistic as realism.

At Alpbach in 1964, Feyerabend and Feigl jointly directed a seminar on the recent development of analytic philosophy. There Feyerabend re-encountered the leading light of the Logical Positivist movement, Rudolph Carnap (whom he had already met at UCLA). Carnap tried to convince Feyerabend

of the virtues of clarity, but failed. Feyerabend was still attached to ‘scientific’ philosophy, and considered philosophy worthless unless it made a positive and quantifiable contribution to the growth of knowledge (which, of course, meant science).

But a seminar in Hamburg in 1965, at which Feyerabend discussed the foundations of quantum theory with the physicist C.F. von Weizsäcker, did have a lasting, if somewhat delayed, impact:

> Von Weizsäcker showed how quantum mechanics arose from concrete research while I complained, on general methodological grounds, that important alternatives had been omitted. The arguments supporting my complaint were quite good... but it was suddenly clear to me that imposed without regard to circumstances they were a hindrance rather than a help: a person trying to solve a problem whether in science or elsewhere *must be given complete freedom* and cannot be restricted by any demands, norms, however plausible they may seem to the logician or the philosopher who has thought them out in the privacy of his study. Norms and demands must be checked by research, not by appeal to theories of rationality. In a lengthy article I explained how Bohr had used this philosophy and how it differs from more abstract procedures. Thus Professor von Weizsäcker has prime responsibility for my change to ‘anarchism’ - though he was not at all pleased when I told him so in 1977. (*SFS*, p.117).

The Impact of the ‘Student Revolution’.

The mid-to-late 1960s was a time of ferment in Western culture, and Feyerabend was in the thick of it. In Berkeley, naturally, he ran into the Free Speech Movement, and he encountered the ‘student revolution’ there too, as well as in London and Berlin. This obviously fired his interest in political philosophy, more especially in political questions about science. Of his post at Berkeley, he later said:

> My function was to carry out the educational policies of the State of California which means I had to teach people what a small group of white intellectuals had decided was knowledge. (*SFS*, p.118).

However, Feyerabend's experience under these educational policies was undoubtedly one of the defining periods of his intellectual life, a time in which he became deeply suspicious of these intellectuals and ‘Western rationalism’ as a whole:

> In the years 1964ff. Mexicans, Blacks, Indians entered the university as a result of new educational policies. There they sat, partly curious, partly disdainful, partly simply confused hoping to get an ‘education’. What an opportunity for a prophet in search of a following! What an opportunity, my rationalist friends told me, to contribute to the spreading of reason and the improvement of mankind! I felt very differently. For it dawned on me that the intricate arguments and the wonderful stories I had so far told to my more or less sophisticated audience might just be dreams, reflections of the conceit of a small

> group who had succeeded in enslaving everyone else with their ideas. Who was I to tell these people what and how to think? (ibid. See also *KT*, p.123).

At this time, Feyerabend gave two lectures, one on general philosophy, and one on philosophy of science. He seems to have got into some trouble at Berkeley by running his seminar on unacceptably loose lines, regularly cancelling lectures, and failing to prepare for the lectures he did give:

> I often told the students to go home--the official notes would contain everything they needed. As a result an audience of 300, 500, even 1,200 shrank to 50 or 30. I wasn't happy about that; I would have preferred a larger audience, and yet I repeated my advice until the administration intervened. Why did I do it? Was it because I disliked the examination system, which blurred the line between thought and routine? Was it because I despised the idea that knowledge was a skill that had to be acquired and stabilized by rigorous training? Or was it because I didn't think much of my own performance? All these factors may have played a role. (p.122).

But although he sympathised with the original aims of the student movement, Feyerabend was unimpressed by their leaders, feeling that their ideas were as authoritarian as those they were trying to replace. He reports having cut fewer lectures during the student strike than either before or afterwards! Nevertheless, by holding his lectures off-campus during this campus war, Feyerabend antagonised the administration that had hired him. Tales of him giving ‘A’ grades to every student in his class, regardless of their production (or lack of it), abound. He had the impression that some of his colleagues, especially John Searle, wanted to have him fired, and that they only gave up when they realised how much paperwork would be involved (p.126).

The Late Sixties.

During the summer of 1966, Feyerabend lectured on church dogma at Berkeley. (‘Why church dogma? Because the development of church dogma shares many features with the development of scientific thought’ (pp.137-8)). He eventually turned these thoughts into a paper on ‘Classical Empiricism’, published in 1970, in which he argued that empiricism shared certain problematic features with protestantism. He had already come some way from his 1965 defence of a ‘disinfected’, ‘tolerant’ form of Empiricism. The publication, in 1969, of the four- page article, ‘Science Without Experience’, which argued that in principle experience is necessary at *no* point in the construction, comprehension or testing of empirical scientific theories finally gave notice that Feyerabend was no longer concerned to present himself as any kind of empiricist.

Despite taking his academic duties and responsibilities decreasingly seriously, and coming into conflict with his own university's administration as a result, Feyerabend had not yet fouled his substantial reputation as a serious philosopher of science. He reports that he received job offers from London, Berlin, Yale, and Auckland, that he was invited to become a fellow of All Souls College, Oxford, and that he corresponded with Friedrich von Hayek (whom he already knew from the Alpbach seminars)

about a job in Freiburg (p.127). He accepted the posts in London, Berlin, and Yale. In 1968, he resigned from UC Berkeley and left for Minneapolis, but grew homesick, got re-appointed, and returned to Berkeley almost immediately.

In London, lecturing to University College and the LSE, he met Imre Lakatos. The two became great friends, corresponding with one another regularly and voluminously until Lakatos' death. Feyerabend recalls that Lakatos, whose office was across the corridor from the LSE lecture hall, used to intervene in his lectures when Feyerabend made a point he disagreed with (*SFS*, p.13, *KT*, p.128).

Against Method (1970-75).

After stints in London, Berlin, and Yale (all of them running alongside his post at UC Berkeley), Feyerabend took up a chair at the University of Auckland, New Zealand, and lectured there in 1972 and 1974 (pp.134-5). He even considered settling down in New Zealand around that time (p.153), although this hardly seems compatible with his jet-setting lifestyle.

By the early 1970s Feyerabend had flown the falsificationist coop and was ready expound his own perspective on scientific method. In 1970, he published a long article entitled ‘Against Method’ in which he attacked several prominent accounts of scientific methodology. In their correspondence, he and Lakatos subsequently planned the construction of a debate volume, to be entitled *For and Against Method*, in which Lakatos would put forward the ‘rationalist’ case that there was an identifiable set of rules of scientific method which make all good science science, and Feyerabend would attack it. Lakatos' unexpected death in February 1974, which seems to have shocked Feyerabend deeply, meant that the rationalist part of the joint work was never completed.

Later that year, Feyerabend found himself lecturing at the University of Sussex:

> I have no idea why and how I went to the University of Sussex at Brighton... what I do remember is that I taught two terms (1974/1975) and then resigned; twelve hours a week (one lecture course, the rest tutorials) was too much. (p.153).

A member of Feyerabend's audience recalls things in rather more detail:

> Sussex University: the start of the Autumn Term, 1974. There was not a seat to be had in the biggest Arts lecture theatre on campus. Taut with anticipation, we waited expectantly and impatiently for the advertized event to begin. He was not on time - as usual. In fact rumour had it that he would not be appearing at all that illness (or was it just ennui? or perhaps a mistress?) had confined him to bed. But just as we began sadly to reconcile ourselves to the idea that there would be no performance that day at all, Paul Feyerabend burst through the door at the front of the packed hall. Rather pale, and supporting himself on a short metal crutch, he walked with a limp across to the blackboard. Removing his sweater he picked up the chalk and wrote down three questions one beneath the other:

> What's so great about knowledge? What's so great about science? What's so great about truth? We were not going to be disappointed after all!
>
> During the following weeks of that term, and for the rest of his year as a visiting lecturer, Feyerabend demolished virtually every traditional academic boundary. He held no idea and no person sacred. With unprecedented energy and enthusiasm he discussed anything from Aristotle to the Azande. How does science differ from witchcraft? Does it provide the only rational way of cognitively organizing our experience? What should we do if the pursuit of truth cripples our intellects and stunts our individuality? Suddenly epistemology became an exhilarating area of investigation.
>
> Feyerabend created spaces in which people could breathe again. He demanded of philosophers that they be receptive to ideas from the most disparate and apparently far-flung domains, and insisted that only in this way could they understand the processes whereby knowledge grows. His listeners were enthralled, and he held his huge audiences until, too ill and too exhausted to continue, he simply began repeating himself. But not before he had brought the house down by writing 'Aristotle' in three-foot high letters on the blackboard and then writing 'Popper' in tiny, virtually illegible letters beneath it! (John Krige, *Science, Revolution and Discontinuity*, (Sussex: Harvester Press, 1980), pp.106-7).

Because his health was poor, Feyerabend started seeing a healer who had been recommended to him. The treatment was successful, and thenceforth Feyerabend used to refer to his own case as an example of both the failures of orthodox medicine and the largely unexplored possibilities of 'alternative' or traditional remedies.

Instead of the volume written jointly with Lakatos, Feyerabend put together his tour de force, the book version of *Against Method* (London: New Left Books, 1975), which he sometimes conceived of as a letter to Lakatos (to whom the book is dedicated). A more accurate description, however, is the one given in his autobiography:

> *AM* is not a book, it is a collage. It contains descriptions, analyses, arguments that I had published, in almost the same words, ten, fifteen, even twenty years earlier... I arranged them in a suitable order, added transitions, replaced moderate passages with more outrageous ones, and called the result 'anarchism'. I loved to shock people... (pp.139, 142).

The book contained many of the themes mentioned so far in this essay, sprinkled into a case study of the transition from geocentric to heliocentric astronomy. But whereas he had previously been arguing in favour of methodology (a 'pluralistic' methodology, that is), he had now become dissatisfied with *any* methodology. He emphasised that older scientific theories, like Aristotle's theory of motion, had powerful empirical and argumentative support, and stressed, correlatively, that the heroes of the scientific revolution, such as Galileo, were not as scrupulous as they were sometimes represented to be. He portrayed Galileo as making full use of rhetoric, propaganda, and various epistemological tricks in order

to support the heliocentric position. The Galileo case is crucial for Feyerabend, since the 'scientific revolution' is his paradigm of scientific progress and of radical conceptual change, and Galileo is his hero of the scientific revolution. He also sought further to downgrade the importance of empirical arguments by suggesting that aesthetic criteria, personal whims and social factors have a far more decisive role in the history of science than rationalist or empiricist historiography would indicate.

Against Method explicitly drew the 'epistemological anarchist' conclusion that there are no useful and exceptionless methodological rules governing the progress of science or the growth of knowledge. The history of science is so complex that if we insist on a general methodology which will not inhibit progress the only 'rule' it will contain will be the useless suggestion: 'anything goes'. In particular, logical empiricist methodologies and Popper's Critical Rationalism would inhibit scientific progress by enforcing restrictive conditions on new theories. The more sophisticated 'methodology of scientific research programmes' developed by Lakatos either contains ungrounded value-judgements about what constitutes good science, or is reasonable only because it is epistemological anarchism in disguise. The phenomenon of incommensurability renders the standards which these 'rationalists' use for comparing theories inapplicable. The book thus (understandably) had Feyerabend branded an 'irrationalist'. At a time when Kuhn was downplaying the 'irrationalist' implications of his own book, Feyerabend was perceived to be casting himself in the role others already saw as his for the taking. (He did not, however, commit himself to *political* anarchism. His political philosophy was a mixture of liberalism and social democracy).

He later said:

> One of my motives for writing *Against Method* was to free people from the tyranny of philosophical obfuscators and abstract concepts such as 'truth', 'reality', or 'objectivity', which narrow people's vision and ways of being in the world. Formulating what I thought were my own attitude and convictions, I unfortunately ended up by introducing concepts of similar rigidity, such as 'democracy', 'tradition', or 'relative truth'. Now that I am aware of it, I wonder how it happened. The urge to explain one's own ideas, not simply, not in a story, but by means of a 'systematic account', is powerful indeed. (pp.179-80).

The Political Consequences of Epistemological Anarchism: *Science in a Free Society* (1978).

The critical reaction to *Against Method* seems to have taken Feyerabend by surprise. He was shocked to be accused of being aggressive and nasty, so he replied by accusing his accusers of the very same thing. He felt it necessary to respond to most of the book's major reviews in print, and later assembled these replies into a section of his next book, *Science in a Free Society*, entitled 'Conversations with Illiterates'. Here he berated the unfortunate reviewers for having misread *Against Method*, as well as for being constitutionally incapable of distinguishing between irony, playfulness, argument by reductio ad absurdum, and the (apparently rather few) things he had really committed himself to in *AM*. The spectacle of Feyerabend levelling these accusations at others is not itself without irony. (His widow

reports that in his later years, *SFS* was the book he would most like to have distanced himself from). In the commotion surrounding *AM*, Feyerabend succumbed to depression:

> ... now I was alone, sick with some unknown affliction; my private life was in a mess, and I was without a defense. I often wished I had never written that fucking book. (*KT*, p.147).

Feyerabend saw himself as having undermined the arguments for science's privileged position within culture, and much of his later work was a critique of the position of science within Western societies. Because there is no scientific method, we can't justify science as the best way of acquiring knowledge. And the *results* of science don't prove its excellence, since these results have often depended on the presence of non-scientific elements, science prevails only because ‘the show has been rigged in its favour’ (*SFS*, p.102), and other traditions, despite their achievements, have never been given a chance. The truth, he suggests, is that

> science is much closer to myth than a scientific philosophy is prepared to admit. It is one of the many forms of thought that have been developed by man, and not necessarily the best. It is conspicuous, noisy, and impudent, but it is inherently superior only for those who have already decided in favour of a certain ideology, or who have accepted it without ever having examined its advantages and its limits (*AM*, p.295).

The separation of church and state should therefore be supplemented by the separation of science and state, in order for us to achieve the humanity we are capable of. Setting up the ideal of a free society as ‘a society in which all traditions have equal rights and equal access to the centres of power’ (*SFS*, p.9), Feyerabend argues that science is a threat to democracy. To defend society against science we should place science under democratic control and be intensely sceptical about scientific ‘experts’, consulting them only if they are controlled democratically by juries of laypeople.

Ten Wonderful Years: The Eighties in Berkeley and Zurich.

Out of all Feyerabend's many academic positions, perhaps the one he enjoyed most was his tenure throughout the 1980s at the *Eidgenössische Technische Hochschule*, Zurich. Feyerabend applied for the post after his friend Eric Jantsch had told him that the Polytechnic was looking for a philosopher of science. The selection process was, by Feyerabend's account, very long and somewhat involved (pp.154ff.). Having recently left another post in Kassel, he apparently gave up hopes of being hired by the Swiss, and ‘decided to remain in Berkeley and stop moving about’ (p.158). But, after several stages in the decision-making procedure, he was finally given the job, and ‘ten wonderful years of half-Berkeley, half-Switzerland’ (p.158) turned out to be exactly what he had been looking for. At Zurich he lectured on Plato's *Theaetetus* and *Timaeus,* and then on Aristotle's *Physics*. The two-hour seminars, many of which were organised by Christian Thomas (with whom Feyerabend was to edit anthologies) were run on the same lines as Berkeley: no set topic, but presentations by the participants (p.160). Feyerabend later considered this to be the period in which he ‘got his intellectual act together’ (p.162), meaning that he recovered from the critical reactions to *Against Method* and was finally freed from the

necessity of defending it against all criticism. However, this didn't seem to have affected his attitude towards work: in Zurich he refused offers of an office, because no office meant no office hours, and therefore no waste of time (pp.131, 158)!

Many of the more important papers Feyerabend published during the mid- 1980s were collected together in *Farewell to Reason* (London: Verso, 1987). The major message of this book is that relativism is the solution to the problems of conflicting beliefs and of conflicting ways of life. Feyerabend starts by suggesting that the contemporary intellectual scene in Western culture is by no means as fragmented and cacophonous as many intellectuals would have us believe. The surface diversity belies a deeper uniformity, a monotony generated and sustained by the cultural and ideological imperialism which the West uses to beat its opponents into submission. Such uniformity, however, can be shown to be harmful even when judged by the standards of those who impose it. Cultural diversity, which already exists in some societies, is a good thing not least because it affords the best defence against totalitarian domination.

Feyerabend proposes to support the idea of cultural diversity both positively, by producing considerations in its favour, and negatively ‘by criticising philosophies that oppose it’ (*FTR*, p.5). Contemporary philosophies of the latter type are said to rest on the notions of *Objectivity* and *Reason*. He seeks to undermine the former notion by pointing out that confrontations between cultures with strongly held opinions which are each believed by members of the cultures in question to be objectively true can turn out in different ways. The result of such confrontation may be the persistence of the old views, fruitful and mutual interaction, relativism, or argumentative evaluation. ‘Relativism’ here means the decision to treat the other people's form of life and the beliefs it embodies as ‘true-for-them’, while treating our own views as ‘true-for-us’. Feyerabend feels that this is an appropriate way to *resolve* such confrontation.

Admittedly, these outcomes are indeed possible. But this does not establish any form of relativism. Indeed, we might as well turn the argument around, and say that the possibility of the dispute being resolved by one participant freely coming around to the other's point of view shows the *un*tenability of relativism.

Feyerabend complains that the ideas of reason and rationality are ‘ambiguous and never clearly explained’ (*FTR*, p.10); they are deified hangovers from autocratic times which no longer have any content but whose ‘halo of excellence’ (ibid.) clings to them and lends them spurious respectability:

> [R]ationalism has no identifiable content and reason no recognisable agenda over and above the principles of the party that happens to have appropriated its name. All it does now is to lend class to the general drive towards monotony. It is time to disengage Reason from this drive and, as it has been thoroughly compromised by the association, to bid it farewell. (*FTR*, p.13).

Relativism is the tool with which Feyerabend hopes to ‘undermine the very basis of Reason’ (ibid.). But

is it Reason with a capital ‘R’, the philosophers' abstraction alone, that is to be renounced, or reason itself too? Feyerabend is on weak ground when he claims that ‘Reason’ is a philosophers' notion which has no content, for it is precisely the philosopher who *is* willing to attach a specific content to the formal notion of rationality (unlike the layperson, whose notion of reason is closer to what Feyerabend calls the ‘material’ conception, where to be rational is ‘to avoid certain views and to accept others’ (ibid., p.10)).

Relativism is a result of cultural confrontation, an ‘attempt to make sense of the phenomenon of cultural variety’ (*FTR*, p.19). Feyerabend is well aware that the term ‘relativism’ itself is understood in many different ways. But his attempt to occupy a substantial yet defensible relativist position is a failure. At some points he merely endorses views which no-one would deny, but which do not deserve to be called relativist (such as the idea that people may profit from studying other points of view, no matter how strongly they hold their own view (*FTR*, p.20)). At others he does manage to subscribe to a genuinely relativist view, but fails to show why it must be accepted.

It was only in 1988, on the 50th anniversary of Austria's unification with Germany, that Feyerabend became interested in his past (p.1). The Feyerabends left California for life in Switzerland and Italy in the fall of 1989 (p.2). It was during this move that Feyerabend re-discovered his mother's suicide note (p.9), which may have been one of the factors that spurred him to write his autobiography. Feyerabend looked forward to his retirement, and he and Grazia decided to try to have children. He claimed to have forgotten the thirty-five years of his academic career almost as quickly as he had earlier forgotten his military service (p.168).

Feyerabend in the Nineties.

Feyerabend published a surprisingly large number of papers in the 1990s (although many of them were short ones with overlapping content). Several appeared in a new journal, *Common Knowledge*, in whose inauguration he lent a hand, and which set out to integrate insights from all parts of the intellectual landscape.

Although these papers were on scattered subjects, there are some strong themes running through them, several of which (as I have argued elsewhere (Preston [forthcoming])) bear comparison with what gets called ‘post-modernism’. Here I shall sketch only the main ones.

One of the projects which Feyerabend worked on for a long time, but never really brought to completion, went under the name ‘The Rise of Western Rationalism’. Under this umbrella he hoped to show that Reason (with a capital ‘R’) and Science had displaced the binding principles of previous world-views *not* as the result of having won an argument, but as the result of power-play. While the first philosophers (the pre-Socratic thinkers) had interesting views, their attempt to replace, streamline or rationalise the folk-wisdom which surrounded them was eminently resistible. Their introduction of the appearance/reality dichotomy made nonsense of many of the things people had previously known. Even nowadays, indigenous cultures and counter-cultural practices provide alternatives to Reason and that nasty Western science.

However, Feyerabend recognised that this is to present science as too much of a monolith. In most of his work after *Against Method*, emphasises what has come to be known as the ‘disunity of science’. Science, he insists, is a collage, not a system or a unified project. Not only does it include plenty of components derived from distinctly ‘non-scientific’ disciplines, but these components are often vital parts of the ‘progress’ science has made (using whatever criterion of progress you prefer). Science is a collection of theories, practices, research traditions and world-views whose range of application is not well-determined and whose merits vary to a great extent. All this can be summed up in his slogan: "Science is not one thing, it is many".

Likewise, the supposed ontological correlate of science, ‘the world’, consists not only of one kind of thing but of countless kinds of things, things which cannot be ‘reduced’ to one another. In fact, there is no good reason to suppose that the world has a single, determinate nature. Rather we inquirers construct the world in the course of our inquiries, and the plurality of our inquiries ensures that the world itself has a deeply plural quality: the Homeric gods and the microphysicist's subatomic particles are simply different ways in which ‘Being’ responds to (different kinds of) inquiry. How the world is ‘in-itself’ is for ever unknowable. In this respect, Feyerabend's last work can be thought of as aligned with ‘social constructivism’.

Conclusion: Last Things.

Feyerabend's autobiography occupied him right up until his death on February 11th, 1994, at his home in Meilen on Lake Zurich. At the end of the book, he expressed the wish that what should remain of him would be ‘*not* papers, *not* final declarations, but love’ (p.181).

His autobiography was published in 1995, his last book *The Conquest of Abundance*, is now being prepared, and a third volume of his *Philosophical Papers* will appear in 1998.

Although the focus of philosophy of science has moved away from interest in scientific methodology in recent years, this is not due in any great measure to acceptance of Feyerabend's anti-methodological argument. His critique of science (which gave him the reputation for being an ‘anti-science philosopher’, ‘the worst enemy of science’, etc.) is patchy. Its flaws stem directly from his scientific realism. It sets up a straight confrontation between science and other belief-systems as if they are all aiming to do the *same* thing (give us ‘knowledge of the world’) and must be compared for how well they deliver the goods. A better approach would be, in Gilbert Ryle's words, ‘to draw uncompromising contrasts’ between the businesses of science and those of other belief-systems. Such an approach fits far better with the theme Feyerabend approached later in his life: that of the disunity of science.

Feyerabend came to be seen as a leading cultural relativist, not just because he stressed that some theories are incommensurable, but also because he defended relativism in politics as well as in epistemology. His denunciations of aggressive Western imperialism, his critique of science itself, his conclusion that ‘objectively’ there may be nothing to choose between the claims of science and those of

astrology, voodoo, and alternative medicine, as well as his concern for environmental issues ensured that he was a hero of the anti-technological counter-culture.

Different components and phases of Feyerabend's work have influenced very different groups of thinkers. His early scientific realism, contextual theory of meaning, and the way he proposed to defend materialism were taken up by Paul and Patricia Churchland. Richard Rorty, for a time, also endorsed eliminative materialism. Feyerabend's critique of reductionism has influenced Cliff Hooker and John Dupré, and his general point of view influenced books such as Alan Chalmers' well-known introduction to philosophy of science *What is this thing called science?* (Milton Keynes: Open University Press, 1978).

Feyerabend has also had considerable influence within the social studies. He directly inspired books like D.L.Phillips' *Abandoning Method* (San Francisco, 1973), in which the attempt was made to transcend methodology. Less directly, he has exerted enormous influence on a generation of sociologists of science through his relativism, social constructivism, and apparent irrationalism. It is still far too early to say whether, and in what way, his philosophy will be remembered.

3. Feyerabend's Major Writings

- 'Problems of Empiricism', *Beyond the Edge of Certainty: Essays in Contemporary Science and Philosophy*, ed. R.G.Colodny (New Jersey: Prentice-Hall, 1965), pp.145-260.
- *Against Method* (London: Verso, 1975).
- *Science in a Free Society* (London: New Left Books, 1978).
- *Realism, Rationalism, and Scientific Method: Philosophical Papers, Volume 1* (Cambridge: Cambridge University Press,1981).
- *Problems of Empiricism: Philosophical Papers, Volume 2* (Cambridge: Cambridge University Press, 1981).
- *Farewell to Reason* (London: Verso/New Left Books, 1987).
- *Against Method* (London: 1975); Revised edn (London: Verso, 1988).
- *Three Dialogues on Knowledge* (Oxford: Basil Blackwell, 1991).
- *Killing Time: The Autobiography of Paul Feyerabend*, (Chicago: University of Chicago Press, 1995).
- *Conquest of Abundance: A Tale of Abstraction Versus the Richness of Being*, ed. B.Terpstra (Chicago: University of Chicago Press, 1999).
- *Knowledge, Science and Relativism: Philosophical Papers, Volume 3*, ed. J.Preston, (Cambridge: Cambridge University Press, 1999).

John Stuart Mill

John Stuart Mill (1806-1873), British philosopher, economist, moral and political theorist, and administrator, was the most influential English-speaking philosopher of the nineteenth century. His views are of continuing significance, and are generally recognized to be among the deepest and certainly the most effective defenses of empiricism and of a liberal political view of society and culture. The overall aim of his philosophy is to develop a positive view of the universe and the place of humans in it, one which contributes to the progress of human knowledge, individual freedom and human well-being. His views are not entirely original, having their roots in the British empiricism of John Locke, George Berkeley and David Hume, and in the utilitarianism of Jeremy Bentham. But he gave them a new depth, and his formulations were sufficiently articulate to gain for them a continuing influence among a broad public.

1. Life

John Stuart Mill was born in Petonville, then a suburb of London. He was the eldest son of James Mill, a Scotsman who had come to London and become a leading figure in the group of philosophical radicals which aimed to further the utilitarian philosophy of Jeremy Bentham. John Stuart Mill's mother was Harriet Barrow, who seems to have had very little influence upon him. James Mill's income was at first slight, as he struggled to make his living as a reviewer. But his *History of India* secured him a position in the East India Company and he rose to the post of Chief Examiner, in effect the chief administrator of the Company. In spite of these duties and the work they entailed James spent considerable time on the education of his eldest son. The latter began to learn Greek at three and Latin at eight. By the age of fourteen he had read most of the Greek and Latin classics, had made a wide survey of history, had done extensive work in logic and mathematics, and had mastered the basics of economic theory. This education was undertaken according to the principle of Bentham's associationist psychology, and aimed to make of the younger Mill a leader in views of the philosophical radicals.

At fifteen John Stuart Mill undertook the study of Bentham's various fragments on the theory of legal evidence. These had an inspiring influence on him, fixing in him his life-long goal of reforming the world in the interest of human well-being. At eighteen he spent considerable time and effort at editing these manuscripts into the long coherent treatise that they became in his hands. Guided by his father he threw himself into the work of the philosophical radicals, and began an active literary career. Shortly thereafter, in 1823, his father secured him a junior position in the East India Company. He rose in the ranks, eventually to occupy his father's position of Chief Examiner. A visit to France in 1820 had made Mill thoroughly fluent in the language, and he became a life-long student of French thought and history.

In 1826, Mill suffered a sudden attack of intense depression. This lasted for many months. He continued his work, but internally felt that his former goals were without worth. He came to believe that his capacity for emotion had been severely weakened by his father's rigorous training in analysis. His intellect had been educated but not his feelings. In the reading of Wordsworth's poetry he found something of the cure that he needed, and the depression gradually disappeared.

Mill met Gustave d'Eichtahl in 1828. D'Eichtahl was a follower of St. Simon, and introduced Mill to the latter and to works of Auguste Comte. Mill also met John Sterling who was a disciple of Coleridge. Though these thinkers Mill came to appreciate the role of social and cultural institutions in the historical development of human beings. He became convinced of the Comtean view that social change proceeds through "critical periods," in which old institutions are overthrown, followed "organic periods," in which new forms of social cohesion emerge and are consolidated. He came to believe with these French thinkers that in his own time society was emerging from a critical period. From Coleridge he came to view the educated class as the vehicle for ensuring social cohesion in the emerging organic period.

Mill now saw his task to be that of helping British society to emerge into the coming organic period. The

merely negative polemics of Bentham and his father now seemed very limited. It became necessary not merely to criticize older forms of social organization but to work towards replacing them with something better. Moreover, the defenders of older forms of life should no longer be dismissed as representatives of vested interests. The very fact that the older forms had so long survived meant that they had some good in them, and their defenders should be seen not as reactionaries but as those who continue to recognize that good. If that good is now limited, it still must be acknowledged, and not merely dismissed.

Tactically, the social reformer in critical periods cannot proceed by formulating grand philosophic schemes, however correct they may be in principle. Rather he or she must work for piece- meal reform. Only gradually should general principles be proposed, so that the appearance of radical novelty will be avoided. Mill never abandoned his earlier acceptance of the principle of utility, but now used it positively, not just critically and destructively; he emphasized how it could be deployed constructively, enabling new forms of society to emerge, but ones which incorporate the best of the older forms. He now came to think that the democratic demands of the older radicals had to be tempered with a concern for the dangers which it posed for individualism.

In 1830 Mill was introduced to Harriet Taylor. Her husband was a druggist whose grandfather had once been a neighbor of James Mill. The younger Mill rapidly became intimate with Mrs. Taylor, who came to influence profoundly the rest of his life. She was an invalid who lived apart from her husband. The latter, while he lived, remained remarkably tolerant of the Platonic but very close relationship that Mill and his wife maintained. Mill's father highly disapproved of the connection. When Mill married Mrs. Taylor in 1851 two years after her husband's death there was a complete estrangement from his mother and sisters. Mill reports in his *Autobiography* that Harriet was of crucial significance to his intellectual and moral development. During a trip to Europe in 1858 she died at Avignon, where she is buried. For the rest of his life, Mill spent half a year at a house in Avignon so that he could be near to her grave.

In 1823 Mill had entered the employ of the East India Company as a clerk. India was governed by the Company through correspondence between the Court of Directors in London and the Governors on the subcontinent. This was supervised by the Office of the Examiner of Indian Correspondence. Mill rose through the ranks, and for many years was in charge of the correspondence dealing with the princely states not under the direct rule of the Company. In 1856 he became Chief Examiner, in charge of all correspondence, succeeding another utilitarian, Thomas Love Peacock, who had succeed James Mill. After the Indian Mutiny, the British parliament proposed the dissolution of the Company. Mill prepared a vigorous defense of the Company and of the government that it provided, but it was unsuccessful, and he retired on a reasonable pension in 1858.

In 1865 Mill was elected to the House of Commons. Given his reputation and his previous seclusion, his work was subject to immense attention. His performance was generally acclaimed, but he failed in his attempt at re-election in 1868. He continued to work, as he had earlier in his life, for many radical causes. He was particularly concerned for the status of women. His later work was made easier by the cooperation of Mrs. Taylor's daughter, Helen, who in many respects took the latter's place in Mill's life. A number of his important works were published posthumously by Helen Taylor. Mill died in 1873 at Avignon, where he is buried next to his wife.

Mill made his philosophical reputation with his *System of Logic*, which he published in 1843; this work re-vitalized the study of logic, and provided for the remainder of the century the definitive account of the philosophy of science and social science. This was followed by *The Principles of Political Economy* in 1848; this defined the orthodox form of liberal principles for the next quarter century. In 1861 he published his only systematic treatise in first philosophy. This was his *Examination of Sir William Hamilton's Philosophy*, a comprehensive critique of the latter's rationalism and intuitionism. So effective was Mill's critique that this work effectively dated itself and is now unfortunately neglected. His two best-known works in moral philosophy were *On Liberty* and *Utilitarianism*, which appeared in 1859 and 1861 respectively. These are of continuing significance. His *Considerations on Representative Government*, published in 1851, is perhaps now less important than his essay on *The Subjection of Women* (1869). Mill's partially finished *Autobiography* was published, with additions by Helen Taylor, in 1873. She also saw for the posthumous publication in 1874 of his *Three Essays on Religion*.

2. Language and Logic

In the *System of Logic,* Mill accepts the traditional doctrine that propositions as used to describe the world are divided into subject and predicate terms, or, as he would say, names, joined by a copula, either affirmative or negative. Among names there are singular and general. All names denote, either individuals or the attributes of individuals. Names are either singular or general. A general name connotes an attribute and denotes all individuals which have that attribute. Thus, 'white' connotes the attribute whiteness, and denotes all things that have that attribute. Some singular names only denote; they have no connotation. 'Caesar' is such a name. However, many singular names not only denote, they also have a connotation. Thus, 'the conqueror of Gaul' is a singular name. It denotes the same individual as is denoted by 'Caesar', but unlike 'Caesar' it also connotes; it connotes the attribute of being a conqueror of Gaul. In terms of logic, Mill is less concerned that later thinkers would be about the uniqueness implied by the connotation: Caesar is not only *a* conqueror of Gaul but *the* conqueror.

In a proposition, names are joined by a copula, either affirmative or negative. The meaning of a proposition -- its "import", as Mill says -- is determined by the connotation of its parts, the sole exception being given in the case of proper names, where the meaning is determined by the denotation.

Where the import of a proposition is given by connotation, truth or falsity is determined by denotation. An affirmative proposition is true just in case that the thing or things denoted by the subject term are in the class of things denoted by the predicate term; otherwise it is false. Similarly, a negative proposition is true just in case that no thing denoted by the subject term is a member of the class of things denoted by the predicate term. Things and attributes are always such that any proposition is either true or false and not both. This states the Principles of Non-contradiction and of Excluded Middle. No thing or attribute is such that is can be said to be both wholly itself but also necessarily connected to something other than itself: each thing or attribute is logically and ontologically independent of every other thing or attribute.

Since the holding of these principles depends upon the systematic nature of things and their attributes, it

follows that the truth of these principles is in the end a fact about the world and the things in the world -- the deepest, perhaps, of all metaphysical facts about the world and the entities in it.

The world we talk about in our propositions is the world that we come to know it in our ordinary sense experience or inner awareness. The ontology of the world as reflected in language and logic is the ontology of the world as we know it to be. Knowing the meaning of terms and therefore of the import of propositions is knowing the individuals and attributes which they denote and connote. As we know them in our ordinary experience these individuals and attributes are logically self-contained. The rationalists and the Aristotelians argued that beyond our ordinary experience of things we have intuitions -- "rational" intuitions -- of ontological connections that structure things in ways not apparent in our ordinary sense experience of the world. Empiricism is the claim that there is no such rational intuition and nothing in the ontology of the world beyond what we know in ordinary experience. The world of the empiricist is one without necessary connections among individuals and attributes. It is this deep fact about the world that is the metaphysical basis of the truth of the Principles of Non-contradiction and of Excluded Middle.

There is no metaphysical necessity. All necessity is verbal, a matter of the import of propositions. A proposition is necessarily true in the case of connotative names just in case that the connotation of the names is by convention the same, as in ‘Bachelors are unmarried’. Since the connotations are the same, the set of individuals denoted by the subject term is identical with the set of individuals denoted by the predicate term, and the proposition is true, simply by virtue of the verbal conventions. In the case of proper names, where the terms do not connote, as in ‘Cicero is Cicero’, the individual denoted by the one term is precisely that denoted by the other, and so its truth is again verbal.

This account of the meaning of propositions is not complete. Mill does not consider the contrasting cases of ‘Cicero is Cicero’ and ‘Cicero is Tully’. Since ‘Cicero’ and ‘Tully’ are both proper names and therefore purely denotative, it would seem to follow on Mill’s account that, contrary to fact, the two propositions have the same import. Later logicians would work hard to solve some of these difficulties in Mill’s semantics. They would also have to work on problems arising from connotative proper names ("definite descriptions").

Mill’s empiricist thesis, that all necessity is verbal, has important consequences for his account of logic.

Consider the syllogism:

> Man is mortal
> Socrates is a man
> Ergo, Socrates is mortal

It had been argued by Aristotelean and rationalist defenders of logic as a system of necessary science that it is a science that contributed to the growth of knowledge. The inference from ‘Socrates is a man’ to ‘Socrates is mortal’ is mediated, on this view, by the major premise ‘Man is mortal’ which establishes a

real necessary connection between the minor premise and the conclusion by virtue of itself recording a necessary connection among the attributes connoted by the terms which it contains. This traditional account presupposes that there are necessary connections among attributes, that, in other words, attributes are not logically self-contained. Given Mill's claim that attributes are logically independent, this is wrong and the truth of the major adds nothing to the truth of the particular propositions, 'this man is mortal,' 'that man is mortal', etc., whose conjunction it records. Accepting the major as true is simply a way, on the one hand, of accepting that particulars one already knows share the attributes in question, and, on the other hand, a determination that one will continue to affirm this connection of hitherto unexamined particulars.

On Mill's semantics, then, the major premise 'Men are mortal' of the syllogism is, in its import, semantically equivalent to the extended conjunction:

> Peter is a man and Peter is mortal, & Caius is a man and Caius is mortal, & Cicero is a man and Cicero is mortal, & etc.

It is, in other words a way of asserting an indefinitely long conjunction. Now, an inference

> Peter is a man and Peter is mortal, & Caius a a man and Caius is mortal
>
> Hence, Peter is a man and Peter is mortal

is not a genuine inference, one that is ampliative, yielding an increase of truth. It is only an apparent inference. Given the import as a conjunction of the major premise in the syllogism,

> Man is mortal
> Socrates is a man
> Hence, Socrates is mortal

it follows that this too is only an apparent inference. Thus, logic -- that is, deductive logic or syllogistic -- adds nothing to our knowledge; its rules merely reflect our determination to reason consistently with the ways in which we have reasoned in the past: the rules of formal logic, of syllogistic, are the rules of a logic of consistency.

In contrast, logic as ampliative involves a passage from the knowledge of particulars summarized in the major, or universal premise, to an application of the same rule to a new case. In terms of knowledge, the major premise of a syllogism provides no knowledge beyond what it summarizes about particulars already known. Ampliative inference, that is, inference as a part of a logic of truth, is thus always a passage from particulars to particulars.

3. Induction

Since there are no objective necessary connections among the attributes of phenomena given in ordinary experience, it follows that the only grounds that we have for inferring from a sample to a population or from the past to the future are given by present experience or memory: all ampliative inference is inductive. It follows that such inference can never achieve apodictic certainty. This does not imply, as some have suggested, a scepticism about all events beyond present experience; it does not imply that all such judgments are somehow unreasonable or unjustified. It does imply, however, that our notion of rational justification ought to be adapted to this fact.

Humans find themselves as embodied creatures in the world, making "spontaneous" and "unscientific" inductions about specific unconnected and natural phenomena or aspects of experience. Examples are "fire burns" and "food nourishes". The satisfaction of our desires, and indeed our very survival, depends upon our coming to ascertain, so far as we can, the truth about the natural world in which we find ourselves and about ourselves too. Ascertaining such truth as best we can is the cognitive means we have available for meeting those ends. No judgment aiming at such truth can, however, ever attain apodictic certainty, and so we ought, as reasonable beings at least, to be satisfied with less than that. In the absence of infallible knowledge, we ought as reasonable persons be satisfied with fallible knowledge. And within that framework we ought to find as best we can those rules of inference that on the basis of past experience form the best -- though fallible -- guide to matter of fact truth.

Deductive logic keeps us consistent in our search after matter-of-fact truth; the logic of science -- inductive logic -- provides a set of rules that form the best, though fallible, guide that we can discover for the discovery of new truth. The rules of logic, both deductive and inductive, are rules of the art that has as its end, its cognitive end, the search after truth. All inferences are matters of psychological fact. For this Mill was later criticized by some later philosophers such as Husserl; he was accused of the sin of psychologism. But this is unfair to Mill. The latter is not claiming that the laws of logic are part of the subject-matter of the empirical science of psychology. He is arguing, rather, that the laws of logic, of both deductive logic and inductive logic, are normative, rules or standards about how we ought to reason, or, at least, about how we ought to reason given that we have a concern for matter-of-fact truth.

4. Mill’s Empiricism: The Relativity of Knowledge

Mill argues that the apparatus of logic permits us to define predicates such as ‘unicorn’ that connote attributes that are not present in things given in ordinary experience. Such predicates have no denotation, and any proposition such as ‘this is a unicorn’ is false. More difficult are subject terms which connote but do not denote, e.g., ‘the present king of Mexico’. Mill was not alone in having difficulty with the logic of such terms; it was only with the work of Bertrand Russell on definite descriptions that these problems were solved in a way that could fit with an empiricist account of logic and of meaning.

But Mill’s basic point is clear enough. Language aims to state matters of fact about the world. There are logical terms, such as ‘is’ or ‘is not’ or ‘and’, and non-logical terms. The latter are the subject terms and predicate terms of propositions. There are certain subject terms and predicate terms which are primitive

to this language. All others are somehow defined on the basis of these primitive terms -- leaving aside the details, to be worked out by later logicians, how these rules for introducing non-primitive terms are to be specified. Meanings are a matter of subject terms and predicate terms being hooked as it were to things and their attributes. (Mill is hazy, unfortunately, on relations, but in this he is hardly to be distinguished from any logicians prior to Peirce and Russell.) It is Mill's empiricism that these things and attributes to which the primitive terms of language are hooked are presented to us in ordinary experience, either sensory experience or inner awareness of our own states of consciousness.

Subject terms and predicate terms provide the content of propositions. Assuming that thought is propositional, they thereby define the limits of thought. Mill's empiricism thus determines the limits of what is thinkable. In this sense, all knowledge is relative to us, to our consciousness. We can of course have beliefs and even knowledge of things of which we are not conscious; there are parts of the world that we have never experienced. There are parts of things too small to observe by means of unaided sense; there are things too far to be seen by unaided sense; and there are things, such as the inside of unopened oranges, that we do not see but which we would see were we to do certain things, e.g., cut open the orange. The grounds of such knowledge or beliefs are not direct experience, but rather inference from direct experience. But our knowledge of those things, our beliefs about them, are still relative to us in the sense that we cannot think of them except as similar to or resembling things or attributes of which we are conscious in sense experience or inner awareness.

This much Mill takes for granted in his *System of Logic*. The empiricist framework he defends in detail in the *Examination of Sir William Hamilton's Philosophy*.

Some philosophers, for example, George Berkeley, have argued that the only grounds that can justify beliefs about ordinary things is direct consciousness. Mill rejects such an idealism: there is nothing in the being of attributes of things that ontologically determines that such things when they exist must be sensed.

Mill also rejects the view of other philosophers, e.g., Kant or Sir William Hamiliton, that there are things or entities beyond phenomena. According to these philosophers, phenomena are in fact the effects of such things but those things, as trans-phenomenal or noumenal, are wholly different from those phenomena: they or it constitute the Unknowable cause or causes of the phenomena of which we are ordinarily aware. Among these philosophers, some such as Kant held that all that we can know is that the entities exist as causes of phenomena. Others such as Sir William Hamilton argued that we can know these not only as causes but also as being in themselves characterized by attributes, e..g., the primary qualities, which are also given phenomenally. Finally others, such as Hamilton's follower H. E. Mansel, argued that we can know the Unknowable as having attributes that at once resemble those that are had by ordinary things, e.g., some of the human virtues, but in ways which exceed our human powers to conceive -- the suggestion here is that God, the Unknowable, is just but in a way that exceeds all humanly conceivable forms of justice.

Mill objects to these views in the name of logic: they are simply not consistent with the logic that is appropriate to the claim accepted by these philosophers that all knowledge is relative. In the first place,

the concept of cause is, contrary to Kant and Hamilton, not an *a priori* concept. The concept of cause in its basic sense is acquired through our experience of matter-of-fact regularity: it is one that relates phenomena to other phenomena and not phenomena to noumena. The relativity of knowledge includes the relativity of our knowledge of causal relations, and these philosophers therefore have no grounds for supposing the existence of noumenal entities. As for Hamilton's claim that we have in our phenomenal experience knowledge of attributes of noumenal entities as these are in themselves, Mill has no trouble in showing the logical confusion in this claim. Hamilton wants to have it both ways -- all our knowledge is relative or phenomenal and within this phenomenal realm we can discover concepts which apply absolutely or non-relatively to the noumenal things-in-themselves. Mansel's views receive Mill's particular scorn: if terms are not to be used in their ordinary sense then they ought not be used at all. A being, no matter how powerful, whose acts cannot be described in terms characteristic of human morality, is not one that we can reasonably worship. Mill made his well-known proclamation that "I will call no being good who is not what I mean when I apply that epithet to my fellow creatures, and if such a being can sentence me to hell for not so calling him, then to hell I will go." (*Examination of Sir William Hamilton's Philosophy*, p. 103)

5. Scientific Method

Mill works out the basic principles of experimental science in the *System of Logic*, Book III.

He argues that the rules of scientific method evolve out of the spontaneous inductions about the world that we make as embodied creatures. As we investigate the world to find the best means to satisfy our natural needs and aims, some patterns maintain themselves, others turn out to be false leads. The former guide us in our anticipations of nature, and in our plans; they enable us to infer what will be and what would be if we were to do certain things or if other things were to happen. These patterns that we accept as guides we come to think of as laws: a law is a regularity that we accept for purposes of prediction and contrary-to-fact inference. Out of these ways of experiencing and coming to understand the world grows our account of explanation: to explain a fact is to locate a law under which it can be subsumed.

As we proceed in our efforts to understand and explain the world in which we find ourselves, the generalizations we accept begin to accumulate and interweave. We find, moreover, that there are not only generalizations but also at a more generic level patterns among these generalizations. We discover that as we search out such patterns we are often successful in discovering them. This itself is a pattern, a pattern about patterns, or, as Mill put it, a law about laws, a law to the effect that for all sorts of event there are laws, there to be discovered, which explain those sorts of event. This is a generic law to the effect that for every specific sort of event there is another specific sort to which it is regularly or lawfully connected. As we progress in science we generalize this law about laws to include all sorts of events: it is the Law of Universal Causation. It assures us that for any sort of event there are laws, there in the world, which, if we search diligently enough, we will be able to discover.

Guided by this principle, we also discover -- fallibly, to be sure -- that various rules of inference are more effective than others in generating acceptable causal beliefs. At the specific level, for any sort of event

there are a wide variety of alternative possible determining attributes. We make assumptions -- revisable -- about the possible relevant causes, and identify the actual sort of cause by a process of elimination. Mill provides a detailed study of the various rules of eliminative inference in his well-known "Methods of Experimental Inference" (*System of Logic*, Bk. 2, ch. 9).

At the level of specific sorts of event the rule of enumerative induction -- "from all observed A's are B's infer that all A's are B's" -- is unreliable, often leading us to accept as true generalizations that later turn out to be false. Inferences in conformity to this rule often overlook relevant factors that are the real causes or mistake necessary conditions for sufficient conditions. Because of the variety of possible factors at the specific level, the eliminative methods lead to judgments that are more secure than the judgements which mere enumerative judgments would yield.

For any event, however, if one takes it generically then there are at that level only two alternatives, caused or uncaused. Here there are not a variety of alternatives to be eliminated, and the rule of enumerative induction turns out to be more reliable than at the specific level: we have regularly been successful in finding causes at the specific level and this provides grounds for accepting the generic claim that for all events there are causes to be discovered.

But then, as we extend our researches to a new specific area, the thesis that there are causes to be discovered provides inductive support for the lower-level claim that the result of the eliminative inference has really isolated a cause. There is thus an interplay as it were between eliminative and enumerative methods, with inferences at the specific level providing support for generic-level inferences, and the latter in turn providing support for specific-level inferences. Confirmational support rises up a hierarchy from specific laws to laws about laws, and then down from the laws about laws to the specific laws. Inferences in different specific areas mutually support one another through their joint support of the Law of Universal Causation which provides the grounding principle for inductive inference.

Mill's great opponent about the logic of scientific inference was William Whewell, whose *History of the Inductive Sciences* (1837) Mill had read with considerable care. Whewell argued that acceptance of scientific hypotheses depends first upon their capacity to explain observed phenomena and more specifically upon their capacity to explain phenomena in diverse areas (the "consilience of inductions"). Mill can accept the point about the consilience of inductions, given what he argues about the interplay of enumerative and eliminative reasoning. Further, Mill could accept the importance of hypotheses as working assumptions -- "heuristic devices," in Whewell's terms -- , but he could not accept Whewell's claim that the mere fact that an hypothesis accounts for the data provides safe grounds for accepting it as a true statement of law. To be sure, eliminative methods may often show that a working hypothesis is in fact the only one consistent with the facts, and that it is therefore acceptable as true. But Whewell argued on the basis of the history of science that there are cases of hypotheses where the supposed causes have not been observed and which yet seem to yield explanations of observable phenomena. Such hypotheses involving unobserved causes can be found in inferences about areas too small or too distant to be observed -- Whewell instances the undulatory theory of light. Mill agrees that there are such cases, and even allows that such hypotheses provide useful analogies for the guidance of future research. But so long as the data do not determine a unique hypothesis, such hypotheses cannot be accepted as yielding a

new truth.

For Whewell, consilience is effected by generic hypotheses subsuming under themselves more specific hypotheses. These hypotheses involve generic concepts that, in Whewell's terms, "colligate" the more specific concepts that appear in hypotheses further down the ladder. Genuine progress in science depends not so much upon simple generalization from observed data as from the locating by inventive genius new colligating concepts. Mill does not disagree, but argues, contrary to Whewell, that colligation by itself is no test of truth.

It is Whewell's contention that as new colligating ideas emerge in the history of science, the principles in which they are embedded become necessary. The concepts in these axioms, such as 'cause' or 'force', are *a priori*, and research consists in gradually articulating these concepts into principles the necessity of which becomes more evident over time. What Mill would allow to be the free action of creative genius, Whewell construes as the uncovering by the mind of the divine ideas that provide the formal structure in conformity to which the Unknowable Creator constructs the world of phenomena. It is this necessity deriving from the Divine Creator that guarantees the truth of the basic axioms that organize scientific theories and which ensures the consilience of inductions. Needless to say, Mill rejects this account. The claim that some concepts have their origin *a priori* is inconsistent with the guiding thesis of the relativity of knowledge. Mill does not deny that in the process of scientific investigation, basic axioms become indubitable in the sense that their contraries become inconceivable. But such indubitability is psychological and does not derive from some sort of conformity to divine necessity. The truth of such axioms, if it really does obtain, is a matter of their conformity to the way the phenomenal world is, and mere fact that they are psychologically indubitable to the human mind does not guarantee that: given the relativity of knowledge, even indubitable judgements are fallible.

6. The Science of Psychology: Associationism

Central to both Mill's account of human reason and also to his social projects is his account, deriving from Bentham and his father, of the science of the human mind. This theory of how the human mind derives originally from Aristotle's discussion of associative memory. In Mill's hands it becomes a systematic hypothesis about which regularities govern human learning. Mill himself never wrote a systematic treatise on psychology, but late in his life he reprinted his father's *Analysis of the Phaenomena of the Human Mind* (1829, second edition, ed. J. S. Mill, 1869), with extensive notes revising and correcting his father's work.

The theory proposes that if f and g are regularly presented in experience as standing in relation R, then the habit forms in the mind, that if we have an impression or idea of f then it is accompanied with the idea of g. If R is the relation of spatio-temporal contiguity, then the ideas are joined to form a judgment of regularity, a causal judgment. If R is the relation of resemblance, then the ideas associated in the mind according to resemblance classes. A few experiences of connection will produce a loose connection in the mind. An increased frequency of experienced connection will produce a stronger association in the mind. And so attributes that are logically separate in experience through being repeatedly experienced in

conjunction come to be inseparably connected in the mind.

Mill argues that this theory can account, however sketchily, for our use of language and how it becomes meaningful. If a word ‘w’ comes causally to be associated with a kind f, and f is associated with the resembling kind g, then the presence of f to the mind will call up both the associated kind g and the word w, so that w will come to be associated not only with f but also with g, and in fact with all the kinds that stand in the resemblance relation R to f. In this way words become general, applying to all members of a resemblance class. The mechanisms of association and the relations of resemblance thus come, for Mill, to play the role that abstract ideas played for earlier philosophers.

The habits of causal inference provide ways of anticipating what will occur in the world; that is how we learn what to expect. It is through processes of this sort that we form our spontaneous generalizations such as "fire burns" of "food nourishes." Cognitively, these are inferences that conform to the rules of induction by simple enumeration. And in terms of our adapting to the world, these inferences are acquired purely passively. If this was all there is to Mill’s account to the human mind then the criticism often level by the idealists that it ignores the active element in the human intellect, and presents a simplistic view of human reason.

But Mill’s psychology also includes an account of motivation and action. On this theory, pleasure is the prime motivator, the primary end in itself, and the anticipation of pleasure serves as an immediate cause of bodily motions which in turn bring about that pleasure. Through regular success in attaining pleasure, anticipations of pleasure become associated with the sorts of action that bring about that pleasure. When Mill asserts that people seek pleasure, what he is to be taken to mean is that people seek things other than pleasure but that they seek it because pleasure has become associated with it, and that when the desire is fulfilled they experience the pleasure of satisfied desire. In this sense human welfare consists in satisfied desire.

There is one important feature of Mill’s psychology in which he differed from his father. On his father’s view, a complex idea produced by association is simply a collection is its associated parts. On Mill’s view, however, there is a sort of mental chemistry in which the parts fuse, as it were, into a new sort of mental whole. These new sorts of mental unity emerge from associational processes and have properties which are not had by the properties that appear in the genetic antecedents.

Given the account of association and of action, it is evident that various means to pleasure will become associated with feelings of pleasure. But on Mill’s view, this will not be a mere conjunction; to the contrary, as the association becomes strong enough the two parts will fuse into a new sort of emergent whole. The means will not simply be conjoined to pleasure but will become part of pleasure. And so money, for the miser, becomes not just a means to pleasure but for him part of pleasure, a end in itself.

This account of human action presupposes the acceptance of determinism, which Mill vigorously defends in the *System of Logic*, where he outlines the idea of a naturalistic science of human being. Freedom, Mill argues in Book Six, Ch. 2, which he thought the best in the work, is not the absence of causation but

rather the absence of coercion. In fact the whole point of education is to determine the future free actions of the individual: it aims through the associative processes to determine the person's motives and actions.

This much Mill takes over from earlier thinkers such as Hume. But leaving it here has seemed by some again to render the person passive. Mill takes up this point in detail in *Examination of Sir William Hamilton's Philosophy*. The argument of the critics is that if character and motive are determined by earlier causes, how could a person be said him- or herself to be responsible for his or her actions? Hamilton so argued: the view makes the person a creature of his or her environment. This notion seemed convincing to Mill himself until he came to recognize that among the motives that one could acquire is the motive of self-improvement or self-realization. There are irresistible motives; for these we are not as persons responsible. But there are also resistible motives, and these we can shape and determine. That is, we can shape and determine them provided that we have the desire so to do. One is free if one could have resisted the motives on which one did in fact act, provided there had been good reasons so to do. A motive impairs freedom only if it is irresistible, only if it cannot be blocked by a strong reason against it. The free person is one who is sensitive to good reasons for behaving as he or she does. The second-order ends that lead one to shape one's motives and to develop as an individual became the central feature of Mill's social thinking, and this marks a major break in detail, though, to be sure, not in principle, with the utilitarianism of Bentham and his father. In the *Examination of Hamilton's Philosophy*, Mill vigorously defends the notion of human beings as active in their own self-determination.

This account of human being also provides an answer to those who argue that Mill's picture of human reason makes persons purely passive rather than active as thinkers. For, among the ends that can come to be associated with pleasure is the end of truth; in this way curiosity becomes an end in itself. And the motive for self-improvement will lead us to find, so far as we can, better ways to satisfy that end. We will so educate ourselves that our reasoning will conform, not to the simplistic rules of induction by simple enumeration, but to the more reliable rules of eliminative induction. The charge that Mill fails to take into account the active side of human reason is thus mistaken, resting on a failure to recognize those parts of the psychological theory that deal with motivation.

7. Geometry and Arithmetic

It is within this context that one must place the account of the necessity of geometrical and arithmetical truth that Mill develops in the *System of Logic*.

The truths of geometry and arithmetic had traditionally been taken to be necessary. But they clearly have more than verbal import. They are therefore not necessary truths, given Mill's argument that the only necessity is verbal necessity: on Mill's metaphysics, therefore, they depend for their truth upon the individuals and their attributes of the world as we experience those entities.

The propositions of geometry are empirical. The theorems are deduced from premises which are themselves inductively established. These premises are inexact descriptions of objects in physical space. Insofar as the premises are exact descriptions -- referring, e.g., to exactly straight lines -- they describe

material attributes taken to their limits. Thus, all smooth lines resemble one another with regard to different degrees of curvature, and taking a line to be exactly straight is to neglect the degree of curvature. The proposition, "two straight lines cannot enclose a space", when taken as applying literally, is only inexactly true; taken as exactly true it means something to the effect that "The more closely two smooth lines approach absolute breathlessness and straightness, the smaller the space that they enclose." Mill's views on geometry are close to those of the logical positivists in the twentieth century.

His views on arithmetic are more controversial. These were later to be vehemently disputed by the logician Gottlob Frege, not without good grounds. Mill disagreed with those whom he called Conceptualists, who held that arithmetical truths were truths about psychological states. Mill also agreed with Kant against Nominalists such as Hobbes that the propositions of arithmetic are not true by definition; they are, in Kantian terms, synthetic. But that implies, for Mill, against Kant, that they are *a posteriori*, inductive rather than *a priori*. The only way that Mill could see one holding that they are both synthetic and *a priori*, is to hold that they are truths about rationally intuited forms not presented in ordinary experience. This was the solution that Frege was later to adopt. But Mill on empiricist grounds rejected this sort of Realism. This makes Mill in more recent terminology a nominalist. The problem is that arithmetic seems to have a necessity which is at once more than verbal, as Mill correctly held, but also more than that which attaches to the inductive truths of, say, physics or botany. Mill's ontology of things and attributes is simply not sophisticated enough to permit a solution to this problem.

Mill argues that a number is an attribute of an aggregate of units. This brings him close to Frege's idea that the number of a given class is the class of all classes equinumerous to that given class. But he does not clearly distinguish an aggregate from a class, nor the sum of two numbers from the (Boolean) sum of two classes. Moreover, he takes measurement to be the empirical counting of units, rather than a matter of relations among the members of an ordered dimension. In both cases a more sophisticated account of relational form is necessary, but this was developed only by later logicians. Mill is certainly confused from the point of view of later thinkers such as Frege or Russell. Certainly, the view of the later positivists that mathematical truths are a matter of logical form would fit more comfortably with his empiricism.

What Mill does argue about the necessity of geometry and arithmetic, and, for that matter, the basic axioms of other sciences such as physics and chemistry, is that these principles, while from the point of view of their truth are inductive generalizations, are from the point of view of the thinker matters of psychological necessity. The appeal is to the principles of association. The propositions of geometry and arithmetic record matters of fact that are very deep and invariable in our experience. Our repeated experience of these facts creates in the mind invariable associations. These inseparable connections create in the mind of the knower a sense of the necessity of these propositions. The necessity is there, as Whewell and others insist. But the necessity is one of thought rather than one in the ontological structure of things.

8. Perception and Material Things

In his *Examination of Sir William Hamilton's Philosophy*, Mill applies empiricist principles to the ontology of material things and his associationist principles to their perception.

When we cut open an orange we are presented with certain sensory impressions, shapes, colors and textures with which we were not previously presented. However, we also firmly believe that those parts of the orange were there even when we were not perceiving them. Our experience has so formed our habits of expectation that we not only form the conception of those things as existing when they were not being perceived but firmly believe them so to exist. These are things, parts of the orange, existing unperceived; they are possible sensations, which, through our expectations, have become conditional certainties. Mill refers to these possibilities which are conditional certainties as "permanent possibilities", thus distinguishing them from mere vague possibilities which experience gives us no warrant for reckoning upon.

It is important to note that, while we do not experience these permanent possibilities, they are not mere fictions. To the contrary, as just indicated, Mill carefully distinguishes between the permanent possibilities that constitute ordinary things from the mere or "vague" possibilities that we conjure up in our imagination. The acceptance of these possibilities is a matter of certainty, though, to be sure, a certainty that is conditional, based on inference from what we do actually experience. With regard to the ontology of ordinary objects, Mill is a phenomenalist, but among the parts of those things are unexperienced phenomena.

(Mill's "permanent possibilities of sensation" are what later philosophers such as Bertrand Russell would refer to as "unsensed sensibilia." Mill's phenomenalism is similar to what they were to call "neutral monism." The later philosophers differ in the more sophisticated logical apparatus that they could bring to bear.)

Ordinary things, physical objects, are clusters of sensations, actual and possible, that is, permanent, in Mill's sense. These clusters are lawfully ordered; it is our knowledge of these laws or regularities that make the permanent sensations conditional certainties. The clusters include not only visual but also tactual and other forms of sensation. Ideas of depth arise from associations of kinaesthetic sensations that arise as we move from here to there. At a certain point, here, there are visual sensations of color and shape. At another point there are different visual sensations, perhaps the same color, but a different shape -- things are seen in perspective. Also at the other point that shape is presented not only visually but tactually. Relative to the actual experience of the former the others are conditionally certain possibilities located at the appropriate distance.

When we perceive an orange we have certain visual sensations which through our expectations we refer to a collection that includes not only these actual sensations but also the permanent possibilities that are there but which we are not sensing. A perceiving is in effect an associational inference from given sensations to things taken as clusters of sensory parts, most of which are there as unperceived but permanent parts. Like all inferences those inferences are associations of ideas. But these perceivings are so ingrained as to be in effect instantaneous. The ideas which are their parts fuse into a single whole. Through the chemistry of association the perceiving of an ordinary thing is an emergent unity, a new

whole which has that thing as its cognitive or intentional object.

In experience we often find that whenever a given cluster of certified possibilities of sensation obtains, then a certain other cluster follows. In such a context through a further process of association our ideas of causation, power, and activity become connected not with sensations but with groups of possibilities of sensations. The perceptual object thus comes to be thought of as having the power of producing sensations. It becomes the permanent material source of the sensory data that we actually experience. As far as it goes, this inference is legitimate. But there is a tendency of the human mind to transform this material object into a noumenal object that thought somehow to exist apart from all sensory appearances. But it is precisely this tendency that Mill decries as illegitimate: this is his empiricism. "I assume only the tendency, but not the legitimacy of the tendency, to expand all the laws of our own experience to a sphere beyond our experience" (*Examination of Sir William Hamilton's Philosophy*, Ch. XI, p. 187n).

9. Minds

There are two cases, other minds and one's own. Mill discusses both in the *Examination of Sir William Hamilton's Philosophy* (Ch. XII, Appendix).

Among the bodies to which one refers one's sensations, there is one that is as it were peculiar. That is, one stands in a peculiar relationship to it. One is aware of it from the inside. For this body alone one is aware of kinesthetic sensations. One's perceivings locate other bodies at a distance to this one. Our motives and volitions move this body directly in ways that they can move no other body.

Now, there are regularities that connect outward actions of one's body with states of consciousness within that body. These would include patterns such as this: "Whenever my arm goes up there is a consciousness of my body from the inside that contains a willing that my arm go up." These regularities are verified in one's own case. But they can be used to infer the existence of conscious states within other bodies that exhibit the same outward actions as one's own body. Thus, whenever I observe the arm of another going up I can infer that there is a consciousness of that body from the inside that contains a volition that the arm go up. The regularities that obtain in one's own case render the existence of such conscious states in others conditional certainties.

The inference to other minds is thus perfectly reasonable. It is based on two facts, one the peculiar relationship that one's own conscious states have to one's body and the regularities that obtain in one's own experience between one's own conscious states and one' body. The former accounts for the privacy of conscious states, the latter justifies the inference to the presence of similar private states in others.

It is worth noting that many have suggested that our knowledge of other minds is based on an argument from analogy. On Mill's view this is not so. The inference is a simple causal inference. Nor is it an inference based on a single case. To be sure, the regularities are verified in one's own case, but the facts that verify them are the repeated instances that they describe. Nor is privacy a problem. When I infer

from a bodily state to the presence of another mind, the consciousness to which I infer is an awareness of that body from the inside. Since I am aware of only my own body from the inside and not that of any other, I should expect to consciousness to which I infer to be private to the other person.

As for the problem of mind in one's own case, this is more difficult. What is mind? Matter is resolved by Mill into a lawfully related bundle of sensations including many permanent possibilities of sensation. Can one's own mind similarly be resolved into a bundle of feelings with a background of permanent possibilities? The problem is that when I expect or remember a state of consciousness I do not simply believe that is has or will exist; it is also to believe that *I myself* have experienced or will experience that state of consciousness. If it is a series or bundle then it is a series or bundle in which a part of the bundle is conscious of the whole. This had been an objection to the bundle view ever since Plotinus used it against the Epicureans. Mill simply accepts the reality of such awareness. If we accept the bundle view, rejecting the common view of mind as a substance, as he thinks we must, then we are reduced to "accepting the paradox that something which *ex hypothesi* is but a series of feelings, can be aware of itself as a series" (*Examination of Sir William Hamilton's Philosophy*, Ch. XII, p. 194). He thus sees himself as driven to "ascribe a reality to the Ego -- to my own Mind -- different from that real existence as a Permanent Possibility, which is the only reality I acknowledge in Matter" (*ibid*.).

10. Moral Sciences

The Sixth and final book of the *System of Logic* is a masterful account of the methodology of the social or moral sciences, one that still repays detailed attention. Its strength derives not only from the thorough and systematic approach to the issues, but also from the fact that Mill himself practised the whole body of these sciences as they then existed, from psychology of course, through economics -- in his own day he was recognized as the leading political economist -- to history and the then emerging science of sociology. He thought as an economist as well as a moral philosopher about socialism, taxation, and democracy, and he thought not merely as a social thinker about the institutions that govern society but also as a colonial administrator and as a politician in his own country.

The basic pattern of explanation -- subsumption under matter-of-fact regularity -- applies to the realm of the social as it does to the physical and the mental. Idealists were of course to raise the possibility that the human escapes the natural casual order, and requires a form of explanation *toto caelo* different from that of the physical sciences. But with his basic arguments for the relativity of knowledge and for the idea that minds are bundles of perceptions, Mill rejects all such proposals. So within his framework, there are no problems in principle with the idea of a natural science of human being. There are problems, to be sure, but they are problems of detail not of principle.

The major problem in the social sciences is that of complexity. For single individuals, the experimental methods can be applied in much the same way that they can be applied in physics or biology: the science of psychology raises no problems. But with large groups those methods cannot be used; the fact that there are a large number of interacting variable precludes that. Other methods are needed. Mill suggests such methods. These proposals depend upon his views on social relations, his ontology of social structures, if

you wish.

According to Mill "the effect produced, in social phenomena, by any complex set of circumstances, amounts precisely to the sum of the effects of circumstances taken singly" (*Logic*, VI, ix, 1). The same principle does not hold in every science; in chemistry, for example, or in psychology itself, effects often have properties which are not reducible to the properties of the causes. In these cases the laws are said to be "chemical": the resultants have properties that are not present in the causes. But in the case of social phenomena, there is nothing in the resultant whole that is not already in the parts; the resultant whole is simply, as Mill says, the "sum" of the parts. In these cases, then, there is two fold process of inference. First, we consider each cause that is operating and use the science of psychology to infer what effect it would have. Second, we then deduce the laws for the group, that is, the social laws. The deduction is direct, since the social cause is the sum of the individual causes taken as parts, and the social effect is the sum of the individual effects taken as parts.

Thus, it is possible to discover the laws for the group phenomena simply by deducing them from the assumed conjunction of the many single causes. This is what Mill calls the "physical" or "concrete deductive" method (*Logic*, VI, ix). It can be used in political economy, where one assumes everyone is acting on the motive of preferring the greater gain to the smaller (*Logic*, VI, ix, 3). However, in other social phenomena there are many more motives, many more causes, as in sociology and history, and here it is necessary to trace over time the detailed effects of all the many causes. However, this detailed set of inferences is beyond the powers of human computation. The best that we can do is begin with the empirical laws of social phenomena and show by deduction that this was likely to result from what we know of the nature of humankind and the circumstances in which the many individuals then existed. This is the "inverse deductive" method (*Logic*, VI, x, 4).

In either case, however, it is never possible safely to assume that we have located all the causes. That means, in effect, that the laws of social phenomena that we have located are in fact gappy. Social science can therefore never be anything more than a science of *tendencies* rather than one in which positive predictions are possible. This is in fact the best that we can do, given the complexity of the phenomena; but even so, such knowledge can be useful in proposing policy (*Logic*, VI, ix, 2). After all, weather forecasting, too, is useful, even though it too is only a science of tendencies (*Logic*, III, xvii, 2).

It is evident that these methods for investigating social phenomena can work only if the deductions that Mill describes really are valid. Mill, naturally, argues that they are. In fact he holds that they occur elsewhere in science, in physics in particular (*Logic*, VI, ix, 1). Thus, for example, in mechanics it would appear to be possible to deduce the laws for a complex system from the laws for simple systems. If we have a three-body system, we can conceptually divide it into three two-body systems, and knowing the forces that would operate in the two-body systems were they isolated, we can deduce what the forces are that are operating in the three-body system. Mill holds that this deduction proceeds *a priori* (*Logic*, III, vi, xi); in these cases, as opposed to those such as chemistry and psychology where the effect is "heterogeneous" with its causes, "the joint effect of the causes is the *sum* of their separate effects" (*Logic*, III, vi, 2; italics added), and, while we know the law of the separate causes by induction, the inference to their joint effects involves no further induction but only "ratiocination" (*Logic*, III, xi, 1, 2). In fact, in

this matter Mill is simply wrong. In order for the deduction to go through one must take into account the relations by which the simpler systems are constituted into the more complex system, and there is no *a priori* reason for assuming that a given relational structure will yield one sort of law for the complex system rather than another. This means that the deduction of the law for the complex system depends not only upon the laws for the simpler systems but also upon another factual assumption that relates the laws of the complex system to *both* the laws for the simpler systems *and* the relational structure the constitutes the complex system out of the simpler systems. This factual assumption relating the laws for the complex system to both the laws for the simpler systems and the relational structure is itself a law, not a specific causal law but rather *a law about such laws*. Since it is a law the step from the causal laws for the simpler systems is not one of pure ratiocination or pure deduction but also involves an inductive feature. This law, this inductive step the existence of which Mill denies, has been referred to as a "composition law." When Mill asserts that the inference is a deduction that proceeds wholly *a priori* without any inductive step beyond those that provided the laws for the simple systems, he is neglecting to take into account this additional factual premise. In effect this amounts to neglecting the causal role of the relations which constitute the whole out of the parts. Mill, then, is wrong in his claim that in mechanics the deduction of a law for the complex system can be deduced *a priori* from the laws for simpler systems; what he calls the "deductive" method does not in fact have any place in mechanics.

Mill makes a similar mistake in the case of the social sciences. When he claims that the deduction of the laws for the complex social wholes can be deduced *a priori* from the laws for the parts, that is, from the laws for persons taken individually, he is claiming in effect that there is no need for a composition law, or, what amounts to the same, no need to take into account the *social relations* which, by virtue of holding among individuals, constitute the social whole out of those individuals. Mill suggests that in the social sciences, the individual cases act "conjunctively," in just the way that they act in mechanics (*Logic*, VI, ix, 1). But a conjunction is merely that and not a relational whole. Mill also indicates that the inference from the laws of the co-existent causes to the "aggregate" effect is something that we can "calculate *a priori*" (*ibid*.); the inference will, of course, be *a priori* if it proceeds on the basis of a *conjunction* of premises, but not if it requires additional factual premises concerning the relational structure and a composition law. He also suggests, as we have noted, that the total social effect is merely the "sum" of the individual effects. He makes the same point when he explicitly compares social phenomena to those of mechanics. For, he tells us, "in social phenomena the Composition of Causes is the universal law" (*Logic*, VI, vii, 1), where the Composition of Causes is "the principle which is exemplified in all cases in which the joint effect of several causes is identical with the *sum* of their several effects" (*Logic*, III, vi, 1; italics added). In short, when Mill proposes the "deductive" method for the social sciences he is neglecting to take into account social relations as relevant factors. It is much as if Newton failed to take into account the relative positions of the planets when he inferred the forces acting in the solar system from the assumption that gravity would act among the planets and the sun taking them pairwise; but then, Mill's account of mechanics implies that Newton did just that!

Mill was in fact sensitive in his many writings to the role of social relations. He had early in his career supported many of the ideas of Coleridge against the dogmatic social atomism earlier utilitarian radicals. From Coleridge he had learned to appreciate the role of social and cultural institutions in the historical development of human beings. Mill, like his father, was a determinist with regard to social phenomena,

but from Comte he had absorbed the idea that social change proceeds in a series of stages: there are "critical periods," in which old institutions are overthrown, and these are followed by "organic periods," in which new forms of social structure emerge and are consolidated. He felt that in his own time society was emerging from a critical period. It was from his reading of Coleridge on social institutions that Mill came to be aware of the roles that they, especially educational institutions, would play in re-establishing a new social structures, new forms of social relations.

In his work is the social sciences, then, Mill was well aware of the importance of social relations as relevant variables In this he had gone beyond the social atomism of his father. But in his proposals for a methodology of social science he quite neglected the role of those social relations. In his methodological pronouncements has had not yet freed himself from those atomistic assumptions.

It was only later that methodologists came to recognize that the way to deal with the complexity of social phenomena and therefore the inevitable gappiness of the laws that we can discover is through the use of statistical methods.

11. Political Economy

In political economy Mill built upon the foundations laid down by Ricardo, Malthus and his father. His *Principles of Political Economy and some of the applications to Social Philosophy* (1848) was the leading economics textbook for many years. Mill's reasoning generally followed that of Ricardo and Malthus, but was more realistic, allowing that beyond the motive of pecuniary gain and economic self-interest, there were other, higher motives that could play a role, and that moreover institutional forms and even sheer habit might also be relevant. These concerns, and well as his greater methodological insights, led him to challenge the claims of the classical school that wages, rent and profit are the result of immutable laws: there may be laws about wages, but there is no "iron law" of wages. These laws are, to the contrary, the result of institutional constraints, and these institutions can be changed, if the will be there. He came to regard the Malthusian principle of population not as an immutable law and a barrier to progress, but as showing the conditions under which progress can be achieved. His book is throughout governed by his belief in the possibility of great social improvements, combined with a determination to expose simplistic remedies and uncomfortable truths.

In analytical theory, Mill at first differed little from Ricardo, but in later editions of his *Principles* he came to modify those views. Thus, for example, the theory of the wages fund was modified almost to the point of rejection under the criticisms of William Thomas Thornton. Where Mill first adopted Ricardo's view that the average wage is determined by a fixed lot of capital divided by the number of workers, he came to allow that other factors play a role in determining wages, among them workers' expectations as well as various institutional factors.

Mill emphasized the distinction between production and distribution: there are laws in both cases, but these laws are different in kind. The laws of the former, he argued, "partake of the character of physical truths ... . It is not so with the Distribution of Wealth. That is a mater of human institution merely"

(*Principles*, p. 199). The way goods are distributed depends upon the rules of property, and Mill explores various sorts of property relations, from the usual form of his own country, to the ways of holding property in Ireland and India, to the various forms of socialism. The rules that obtain at any given time or place "are what the opinions of the ruling portion of the community makes them" (*ibid*., p. 200); but these in turn are "not a matter of chance" (*ibid*.). To the contrary, they have causes and these can be understood using the methods of empirical science: they are "as much a subject for scientific enquiry as any of the physical laws of nature" (*ibid*., p. 21). However, though Mill emphasizes how production and distribution differ, he holds that production too depends upon social factors. For example, security and monetary incentives are among the things that influence productivity.

From more recent perspectives in economic analysis, some of Mill's economics decidedly looks backward. Thus, Mill retains the now abandoned distinction between productive and unproductive labour. But if this has no place in pure economics, it does have a legitimate place in Mill's work. For Mill the distinction is related to his concern to eliminate vestiges of feudalism, the primitive sector of the economy in which retainers and menial servants are maintained more or less in idleness. This concern recommends the development of the more advanced industrial at the expense of the pre-industrial sector. Mill's economics should be seen as concerned as much with the economics of development as it is with pure theory. Nor is Mill's concern simply with the production of material goods: Book 4, Ch. 6 of the *Principles* ("Of the Stationary State") ends with a moving plea for the preservation of natural beauty.

On the whole Mill supported the laissez faire economic policies that had been defended by earlier economists such a his father and David Ricardo. His overall concern was here as elsewhere with self development, and laissez faire policies seemed to provide the scope needed for individual freedom. But on further reflection, moved in this by his wife, he came to the view that personal development required not just the freedom of the economic market but also political freedom, and that this is of little use to an individual who lacks economic security and opportunity. Mill was concerned, too, with motivation. He saw the system of wages that had developed in the industrial revolution as one which robbed the workers of any interest in the goods that they were producing. He came increasingly to re-examine the objections to socialism, and came to argue in later editions of the *Principles* that, as far as economic theory was concerned, there is nothing in principle in economic theory that precludes an economic order based on socialist policies. He therefore made the radical proposal that the whole wage system be abolished, and that it be replaced by a cooperative system in which the producers would act in combinations, collectively owning the capital necessary for carrying on their operations, and working under managers who would be responsible overall to them. Like Ricardo, he held that profits in the long run would tend to diminish and that the formation of new capital would thereby come to an end. This would bring industry to a halt and population to a stationary level. The result would be a relatively static form of society. In such a society, Mill hoped, people's thoughts would turn from concerns of self-interest to more socially and humanly worthy ends. In such a state many of our present problems would disappear.

Mill summed up his objective in his *Autobiography* (1873): "how to unite the greatest individual liberty of action, with a common ownership in the raw material of the globe, and an equal participation of all in the benefits of combined labour." (p. 239) In his economic theory Mill no doubt appears to the modern socialist to be a follower of Ricardo and the classical liberal economists, but to the latter, and no doubt to

himself, he was clearly a socialist.

12. Moral Philosophy: Utilitarianism

Throughout his major works and in him many essays, Mill argues that the moral worth of actions is to be judged in terms of the consequences of those actions. In this he contrasts his own view with that of those who appealed to moral intuitions. For some, these intuitions are just that, in which case they have little moral force indeed; they are simply the arbitrary feelings of approbation and disapprobation. But intuitions conflict, and we need some standard to decide which of these feelings is correct. Intuition does not supply that. There are some, however, such as William Whewell or Immanuel Kant, or, later, idealists such as T. H. Green, who claim that there are objective criteria for adjudicating conflicts. These philosophers support their intuitions by appeal to a moral order that pervades the universe, some sort of moral essence or objective demand from the noumenal or transcendental realm. However, given the basic argument that Mill offers for the relativity of all knowledge these claims do not amount to much; they are to be taken no more seriously than those who justify their moral judgments by appeal to "God said so". These opponents all appeal to no more than their private sentiment: this is what I like or this is what I dislike. That fact that it *appears* as a moral authority gives it no superior authority.

Moral intuitions are said to reveal ends which are superior to those of our worldly nature, superior to mere pleasure and self-interest. Mill of course agrees that our moral feelings often conflict with our inclinations of self-interest. But these feelings are not feelings that are contrary to our pleasure. They like all ends are sought to the extent to which they are enjoyable. It is just that different, and conflicting things, are enjoyable.

Mill can of course account for these divergent feelings and inclinations. On the psychological account of human being that he defends, pleasure and pain are the prime motivators. Other things are sought, at least initially, as means to pleasure or the avoidance of pain. But as the associative mechanisms work, things that are sought as means come to be associated with the ends for which they are means. These things come to be sought as ends in themselves, as parts of pleasure. The variety of ends that persons suggest are morally demanded by their intuitions are simply things that have come to be among those things that are for them part of pleasure, ends that are in conflict with those ends that are other parts of pleasure. The appeal to intuition does not solve the problems of moral philosophy. It is no more than a commonplace of fact, that we feel better about some ends rather than others and that we often feel that our ends are better that those that others have. The real problem is elsewhere: how to resolve the conflict.

All ends are either pleasure or parts or of pleasure. This is a matter of psychological fact. As Mill puts it, "to desire anything, except in proportion as the idea of it is pleasure, is a physical and metaphysical impossibility" (*Utilitarianism*, Ch. 4). This implies that pleasure is the end of morality:

> The sole evidence it is possible to produce that anything is desirable [= worthy of desire], is that people do actually desire it. If the end which the utilitarian doctrine proposes to itself were not, in theory and in practice, acknowledged to be an end, nothing could ever

> convince any person that it was so (*Utilitarianism*, Ch. 4).

Mill's point is often criticized as making an illegitimate inference from "is" to "ought," from "is desired" to "is worthy of desire." It does indeed make that inference, but it does so legitimately. Mill's point is that, as a matter of lawful fact about human beings, we *must* seek pleasure, it is unreasonable to suggest that anything else could be morally demanded of us. Mill is here relying on the principle that *must implies ought*, the converse of the principle that *ought implies can*. If these principles did not govern our moral attitudes, we would end up attempting the impossible, and, if the point of morality is to guide action, then that is unreasonable: any action attempting the impossible is bound to be pointless.

The maximization of pleasure or happiness is therefore the moral end. But this ought not to be taken in simplistic terms. Mill's is not a crude hedonism. In the first place, it is not crude sensual pleasure that is the aim. Rather, welfare consists in the satisfaction of desire, and the relevant pleasure is the pleasure that comes from satisfied desire. In the second place, when he insists that welfare consists in the experiencing of pleasurable states, he argues, in contrast to what Bentham implied, that quality, not simply the amount of pleasure, is to be taken into account. As Mill came to see in his own experience, reading Wordsworth is better as an experience than drinking ale. As he put it himself, better Socrates dissatisfied than a pig satisfied. Some experiences are qualitatively better than others, and in determining which line of action is better, this has to be part of the calculation. These pleasures are not merely the sum of more elementary pleasures; they are qualitatively different. These differences are a matter of the chemical nature of psychological processes. Among the qualitatively superior ends are the moral ends, and it is in this that people acquire the sense that they have moral intuitions superior to mere self-interest. And in the third place, Mill holds that it is possible to be content with life enough dissatisfied, provided that one has the proper balance of pleasure, reckoned both quantitatively and qualitatively. As he himself suggested, better Socrates dissatisfied than a pig satisfied. The pig may be satisfied, but Socrates' life, even with its dissatisfaction, is preferable. The person who has a good life has a reasonable balance of tranquility, on the one hand, and, on the other, moments o excitement and more intense pleasure.

Human beings collectively develop rules to aid them in their efforts to maximize their happiness. Each of us wants to appropriate goods to satisfy our material needs. But they are scarce, not everyone can satisfy these needs. Given this scarcity of material goods, there will be conflict. If one succeeds in appropriating goods, then others will attempt to take them away to satisfy their own needs. What one more exactly wants is not a maximum of goods but a satisfactory level of goods together with security of tenure. Since each has this an end, norms for the distribution of the scarce goods come to be established. Together with these norms of justice there will also come to be established norms for their enforcement, for the punishment of those who violate these norms. These norms with sanctions attached, that is, the norms of justice will function as means to the satisfaction of material desires, but through the associative mechanisms they will come to sought as ends, as parts of one's pleasure. Because they concern the essential of human well-being, they therefore come to felt as more morally demanding than the principle of utility itself.

The principle of utility judges these norms. Mill is therefore not an "act utilitarian" who holds that the principle of utility is used to judge the rightness or wrongness of each and every act. But neither is he a

"rule utilitarian" who holds that individual acts are judged by various moral rules which are themselves judged by the principle of utility acting as a second order principle to determine which set of rules secures the greatest amount of happiness. For the principle of utility judges not simply rules, according to Mill, but rules with sanctions attached. But Mill holds that there are some occasions on which the principle of utility must be used to judge individual acts. There are two sorts of such occasion. One is to judge when exceptions to ordinary rules are to occur or to judge which subsidiary rule applies when two come into conflict. The other is to judge actions aimed at changing the social structure of rules. It is the leaders in "the ruling portion of the community" who must think and plan in this way, those who are in positions of economic or political or moral power that enables them to sway or determine public feeling and sentiments for social change.

Different forms of such things as agricultural practice will generate different patterns of what will be accepted as norms for distribution; the legitimate ends of justice will be secured by different institutional forms. It is these forms that develop over time through periods of crisis and consolidation.

This consolidation or re-consolidation results in better social forms. Mill in fact argues that such social improvement is the overall trend of development: the direction is to maximize the general well-being. Mill argues that since each person aims to maximize his or her own happiness therefore the overall effect will be to maximize the pleasure of all. As he puts it, since "each person's happiness is a good to that person," then 'the general happiness" must be a good to the aggregate of all persons" (*Utilitarianism*, Ch. 4). It is commonly charged that Mill's inference commits the fallacy of composition -- the fallacy that since this person has a mother, that person has a mother, and that other person has a mother, therefore the aggregate of all persons has a mother. But as he elsewhere explains that "I merely meant in this particular sentence to argue that since A's happiness is a good, B's is a good, C's is a good, etc., the sum of all these goods must be a good (*Later Letters*, p. 1414).

Nor is Mill arguing that since each seeks his or her own happiness, therefore each seeks the happiness of all, though he is often accused of this fallacy. To the contrary, Mill clearly holds that it is seldom true that individuals seek the general happiness. In the best state of society this would be so. But we are clearly not in the best state. In fact, it would be contrary to the principle of utility itself to have individuals constantly seeking the general good. To seek the general good would require constant calculation of long term consequences, and that is hardly possible. If it were attempted, then mistakes would be made and time wasted. Better on utilitarian grounds to work with subsidiary and time-tested rules, with the appeal to utility itself being made only on those relatively rare occasions when subsidiary rules come into conflict or where exceptions are needed, or where whole systems of rules are called into question.

Mill's inference is nonetheless fallacious. It presupposes that the laws for the social whole, the aggregate, are simply the sum of the laws for the individual cases. This is simply an application of the inverse deductive methods that Mill advocates in the *System of Logic*. But this method is fallacious, as we have seen: it ignores the causal role of social relations. Mill in fact in other contexts recognizes this. For he holds that a greater degree of general well-being might be achieved by a different form of social organization.

There is, then, no general justification for the principle of utility. But this does not mean that after all each individual is nothing more than an egoist seeking his or her own happiness and that there is no basis in human nature for a rule capable of resolving conflicts. There is, in the first place, the forms of justice that develop; conformity to these rules which ensure that the needs of others as well as one's own are satisfied, becomes part of the pleasure of each. These systems of rules will often, as in complex modern societies, have rules for changing the rules and magistrates or others in positions of power who can determine how society will change and develop.

But further, in the second place, there is the natural sympathy of human kind, each for the other, or at least the others that are close to us. On this tendency, each is inclined to feel as others feel, so that the ends of others become naturally our own ends. This yields common rather than conflicting ends. In this way the good of all becomes part of the good of each. Each of us thus comes to move in unity with our fellows for the good of each and all.

Our natural sympathy thus works to establish a set of social relations that unite individuals into a community. In his theory Mill may ignore social relations, implicitly denying their existence, but when he comes to consider how society actually works he clearly allows for their existence. In these respects he both looks back to the social atomism of an earlier generation of utilitarian radicals but also, when he admits those relations, makes an advance on their thought.

Sympathy is thus important in insuring that each and all work for a common good. But this common good may not in fact be the best that can be achieved. Sympathy can often be constrained by forms of social order. Greater well being can be achieved only by achieving new forms of social organization. As Mill sees it, the opportunity for such improvement comes in the critical periods of social development. It is in such contexts that moral leaders such as Socrates and Jesus can and have played a crucial role. They can captivate the overall general sympathy present in society to bring about better social structures to be consolidated into improved organic periods.

Utilitarianism is not a simplistic moral principle to be mechanically applied, it is a long term social project.

13. Social and Political Philosophy

For Mill government is not a matter of natural rights or social contract, as in many forms of liberalism. Forms of government are, rather, to be judged according to "utility in the largest sense, grounded on the permanent interest of man as a progressive being" (*On Liberty*, p. 224). By this he means that forms of government are to be evaluated in terms of their capacity to enable each person to exercise and develop in his or her own way their capacities for higher forms of human happiness. Such development will be an end for each individual, but also a means for society as whole to develop and to make life better for all.

Given the centrality of self development, Mill argues that liberty is the fundamental human right. "The

sole end," he proposes, " for which mankind are warranted, individually or collectively... in interfering with the liberty of action of any of their number, is self-protection" (*On Liberty* p. 223). This will enable each to seek his or her own best; it will liberate a diversity of interests to the benefit of the individual and of all; and it will nurture moral freedom and rationality. With the latter will come creativity and the means of social and intellectual progress. Mill's *On Liberty* remains the strongest and most eloquent defense of liberalism that we have. He argues in particular for freedom of thought and discussion. "We can never be sure," he wrote, "that the opinion we are endeavoring to stifle is a false opinion, and if we were sure, stifling it would be an evil still" (*On Liberty*, p. 229).

Bentham and Mill's father had argued that democracy was the form of government that could best secure the happiness of all. The younger Mill was inclined to agree. But the end is not just well-being, as earlier utilitarians argued, though it is that. The end that recommends it is the tendency to foster self-development and individuality. Representative government, is particular, he defended as that form which best encourages individuality. It leads people to take a more active and intelligent participation in society. It provides moral training and encourages the development of natural human sympathies. The result is the habit of looking at social questions from an impersonal perspective rather than that of self-interest. But Mill's defense of democracy was much qualified. To be sure, he was, like the earlier utilitarians, sympathetic to the fall of the *ancien régime* and to the ends of the French Revolution. He had little use for the British aristocracy and criticizes it for its follies in its own country and in Ireland, and the vestiges, such as the Game Laws, of medieval privilege. He strove to liberalize the press still severely bound by an absurd libel law that excluded effective social criticism. But influenced by Coleridge he had come to see that there were virtues in social systems, even out-dated ones, else why would not have survived so long. He therefore came to appreciate the conservative arguments that unrestrained freedom is dangerous. The effort to achieve at year zero a new social order justified on *a priori* principles by means of Jacobin terror can be as great a threat to liberty and to human well-being as the most repressive tyranny.

Mill argued, reasonably on utilitarian grounds, that social institutions need to be adapted to the time and place where they operate. His work in the East India Company dealing with the governance of states in India undoubtedly had a significance influence here. Referring to the rule of Akbar in India, he allowed that despotic rule could be necessary under certain conditions for stable government. He even suggests that, since people must be properly fit if democracy is to function well, a despotic form of government, if well-run with this aim in mind, might prepare its people for the exercise of responsibilities of a free electorate. His position here had some influence on British colonial administrations.

Mill, with de Tocqueville, stressed the importance of local government. He was highly critical of the chaotic forms of local administration then present in Britain, and his influence was effective after 1871 when the central government moved to bring about reforms.

In his thinking about how best to administer a state as a whole, Mill argued that the best administration was one that relied upon professional skills. He was prepared to accept the British form of parliamentary government where the executive is responsible to an elected assembly. Naturally enough, however, he was highly critical of the unelected British House of Lords, which he saw as another vestige of a more

primitive feudal society. The best form of government could be determined by the test of experience and that experience found the Lords wanting.

Individuality and even eccentricity is better than massive social uniformity. The latter is the consequence of both terror and tyranny. But it can also be the consequence of democracy. Influenced by de Tocqueville's analysis of American culture, Mill came to think that the chief danger of democracy is that of suppressing individual differences, and of allowing no genuine development of minority opinion and of minority forms of culture. Democracy might will impoverish the culture of the community by imposing a single and inflexible set of mass values. This form of government has the virtue of fostering intelligence, common moral standards, and happiness; but where the citizens are unfit and passive it can be an instrument for tyranny, perhaps of one, as with Louis Napoleon, or perhaps of the many. In general, the only reliable safeguard can be institutions, educational institutions in particular, that can ensure the development of individuals with personalities strong enough to resist such pressures. But other forms of social order are also called for. Thus, after the rebellion in 1837 in Canada he defended Lord Durham's recommendations for internal responsible self-government in the colonies, free on the whole from interference from the colonial power, with a form of federal organization to defend the cultural interests of the French minority. Another means suggested by Mill for the protection of minorities in a democratic system was a system of proportional representation. Finally, one might also mention his acceptance of the principle of multiple votes, in which educated and more responsible persons would be made more influential by giving them more votes than the uneducated.

Mill is concerned to provide a form of government with as much education as feasible. A properly educated electorate would be willing and able to select the best as their governors. Since those elected would be better informed and wiser on specific issues that those who elected them, it would be wrong to bind the representatives to anything but a very general agreement with the beliefs and the aims of the electors. He agrees with the rejection of populism enunciated by Burke in his speech to his electors in Bristol, accepting the principle that the representative should be expected to exercise his or her own judgement, not merely to accept blindly the views of those on whose votes his or her tenure depended. It was a principle to which Mill himself adhered in his own brief term in the House of Commons.

14. Status of Women

Among the things for which Mill campaigned most strongly were women's rights, women's suffrage, and equal access to education for women. His essay on the *Subjection of Women* (1869) is an enduring defense of gender equality. His strong views in this area led to a deep serious disagreement with his father. To be sure, as one could be expect, he was not able to free himself completely from the prejudices of his age: he argued that it was undesirable that women seek employment outside the home in order to support the family. While Mill argues that not all motives are egoistic and self-interested, he nonetheless held that in most affairs of economics and government such motives are dominant. The elder Mill argued that votes for women were unnecessary, since the male could adequately represent the interests of the family and those who were parts of it. But the younger Mill points out that the interests of the male could diverge from those of the female in the family. Here he recognizes as elsewhere he does not, that the

actions of individuals in an aggregate often do not result in maximizing the general welfare of the parts. The essay can be seen in large part as a long argument on the abuse of power. A well-intentional power *might* secure the interests of the governed, but the power of egoism renders this unlikely. Since male self-interest can conflict with the self-interest of the female, the votes of women are needed to curb the pursuit of male self-interest. Here, as elsewhere, as he says in a letter to Florence Nightengale, "political power is the only security against every form of political oppression." (*Later Letters*, p. 1343-44) In fact, hitherto the interests of the family have been subservient to the interests of the dominant male partner. If the interests of the family, of the aggregate, are to be served, then gender equality is required. Changing the social relations between men and women to ones in which they play equal roles will require each to curb their self-interests and to broaden their social sympathies to include those of the other and of the whole. Mill felt this is his own life: through his relationship with Harriet Taylor, he came to the strong conviction that women's suffrage is an essential step toward the moral improvement of humankind.

15. Views on Religion

Mill was generally taken to be an atheist or an agnostic, though during his life he published little on the topic of religion, and as he made clear in his correspondence with Comte his fear of alienating his readers and losing his public influence led him to be determinedly cautious -- indeed cautious to the extent that he was criticized for this by those who otherwise sympathized with him. The latter were rather consternated, then, with the posthumous publication of Mill's *Three Essays on Religion*: in spite of the strictures that appeared in *Examination of Sir William Hamilton's Philosophy*, it turned out that Mill was rather more sympathetic to religion than were they.

In "On Nature" Mill argues that the maxim "Follow Nature" proposed equally by the ancient Stoics and the modern Romantics is a poor guide to action, certainly one contrary to the principle of utility. 'Nature' might have two meanings. On the first, 'nature' means 'whatever happens', and it recommends as right whatever happens, be it good or bad. In this case, it offers no moral guidance whatsoever. On the second meaning, 'nature' means whatever happens without human interference' -- natural as opposed to artificial in the sense of being the result of human art. In this case it is contradictory since it itself is a matter of human art. Mill argues that nature in the second sense offers us a view of as much evil as good, and so proposes more a challenge to change than an ideal for imitation. The task is not to follow nature but to improve it, especially human nature: virtue is not the consequence of nature but of nurture, of cultivation.

As for nature itself, the only rational conclusion that one can draw from contemplating the amount of ugliness and unavoidable evil that it contains is that whatever principle of good is at work in the universe, if any, cannot subdue the powers of evil: it cannot be omnipotent.

In the essay on "The Utility of Religion" Mill argues that much of the apparent social utility of religion derives not from its dogma and theology but to its inculcation of a widely accepted moral code, and to the force of public opinion guided by that code. The belief in a supernatural power may have had some utility in maintaining that code, but is no longer needed and may indeed be detrimental.

There is an unfortunate tendency in supernatural religion to hinder the development not only of our intellectual, but also our moral nature. Its appeal is to self-interest rather than to disinterested and ideal motives. As with intuitionism in ethics, it stands in the way of the critical evaluation of social norms, and thereby effectively prevents action aimed at social change for the improvement of the human lot in the community. Supernatural religion appeals to the sense of mystery about what lies outside the narrow realm of what we know. But the appeal can be made by poetry: the realm of the unknown can filled only by the imagination. "Religion and poetry address themselves, at least in one of their aspects, to the same part of the human constitution; they both supply the same want, that of ideal conceptions grander and more beautiful than we see realized in the prose of human life" ("Utility of Religion," *Three Essays*, p. 419).

The power of religion to motivate derives, Mill suggests, from the human need for some sort of ideal conception of being to move us to do our best, a standard beyond our common selfish objects of desire. But such purposes can be achieved, and better achieved, by a religion of humanity than can any supernatural religion. It would help us cultivate our feelings and develop our individual capacities, intellectual, moral and emotional, without burdening us with false views about a mysterious Unknowable. The contrast would be to a God of the sort Mansel proposed, one Just beyond all human justice, a principle of Goodness in the world whose existence requires us to deny that the palpable evil that we find really is evil. The religion of humanity would draw our attention to real evil in the world, and urge us to work to overcome it.

These first two essays had been written by 1858; the third, "Theism," was drafted more than a decade later. The first two suggest that the alternative to supernatural religion is not the acceptance of nature and the way things are but the construction of a positive religion of humanity. The third essay makes greater concessions to traditional religion. In this essay Mill evaluates the traditional arguments for the existence of God. He rejects straight out any argument based on an *a priori* causal principle. But he suggests that the order to be found in the universe, in particular the adjustments of organisms for the ends of survival and reproduction, provides grounds for tentatively accepting the existence of a creator. Even here, however, he allows only that it can be established with "no more than probability" that the cause of such order is the activity of some intelligent designer. He allows, too, that one might, contrary to Mansel, characterize the creator in a humanly relevant way as benevolent, though it could be neither omniscient nor omnipotent. For Mill the point about a world created by such a God is that it leaves room for the work of human beings in improving both that world and themselves as persons in it. "If man had not the power," he indicates, "by the exercise of his own energies for the improvement both of himself and of his outward circumstances, to do for himself and other creatures vastly more than god had in the first instance done, the Being who called them into existence would deserve something very different from thanks at his hands." ("Theism," *Three Essays*, p. 458)

Mill argues in the same essay that there is no evidence for the immortality of the soul, but equally none against it. For Mill, this means that there is room for *hope*. Some persons at least do hope, if not for eternal life, then for a life that extends beyond their death. It is possible, he suggests, that the benevolent and powerful (though not all-powerful) creator could grant that wish. Such at least one might hope.

Defenders of religion had long appealed to miracles as support for their beliefs about the supernatural. In his essay Mill is highly critical of such appeals; there is absolutely no evidence that supports such claims. He allows only that a benevolent deity might have indicated an intention to award to those who aspire to it a life after death; if there is no rational evidence in support of that, then one might at least so hope. To this extent he allows that Jesus was indeed miraculously Christ, and that He bore such a message of "glad tidings" for the hopeful.

In spite of Mill's argument that the proper rational attitude towards supernatural religion is neither belief nor disbelief, he now concludes, in his last essay, in a way that many found rather surprising, that "the whole domain of the supernatural is thus removed from the region of Belief into that of simple Hope." ("Theism," *Three Essays*, p. 483) Indeed, such hope might be reasonably be encouraged, since its indulgence might encourage in some persons both the feeling that life is important and their sympathy for others. Further, to construct for oneself or for one's community, an image of a person of high moral excellence, such as Jesus, and from the habit of seeking approval of this person for one's own acts, may aid that "real, though purely human, religion, which sometimes calls itself the Religion of Humanity, and sometimes that of Duty." ("Theism," p. 488) This develops further his concept of the moral significance of cultivating the emotions and reflects the lesson he had learned early in his life, as he recovered from his bout of depression, that human beings can flourish only with the cultivation of the feelings.

In his considerations about the existence of a cause for order in the universe, Mill mentions only in passing the work of Charles Darwin, that natural selection is the cause of apparent design in the natural world. As soon became apparent, this theory removed whatever tentative support Mill had allowed for the existence of a benevolent creator. Hope alone remained the only legitimate religious sentiment, but that hope rested on the sense that there is a creator who might fulfill it. Upon the demise with Darwin's work of any expectation for the existence of such a creator all the slim hopes of religion disappeared. The later Victorians could not share Mill's optimism. They found that all that remained was to shake a fist in rage at the heavens that disappointed and starred back silently.

16. Conclusion

Mill's thought was of a whole. He was consistently empiricist in his metaphysics epistemology, and he developed his moral thinking in this framework. At the same time that moral philosophy shaped his metaphysics. He aimed to show humans the way the world is and how they could accommodate themselves to it and to one another. His aim was the improvement of humankind. His guide was the principle of utility.

This is often missed. The principle of utility has become the object of scholastic discussion. People debate whether Mill's notion that there are some pleasures that are to be preferred to others makes good sense. The human aspect of this ignored. Mill put it well, and makes it clear that his claims on this point are solidly based.

> Few human creatures would consent to be changed into any other lower animals, for a

> promise of the fullest allowance of a beast's pleasures; no intelligent human being would consent to be a fool, not instructed person would be an ignoramus, no person of feeling and conscience would be selfish and base, even though they should be persuaded that the fool, the dunce, or the rascal is better satisfied with his lot than they are with theirs. (*Utilitarianism*, p. 211)

People also critically reject Mill's case for the principle, rejecting it on the grounds that this or that contrived counter-example shows some imperfection in Mill's formulation. But this is to miss the point of Mill's work. There may be imperfections in what was said, but the aim of the whole is clear and criticism should always try to be constructive, not merely negative. Mill himself made clear that nature of the moral imperative that he proposed.

> In the golden rule of Jesus of Nazareth, we read the complete spirit of the ethics of utility. To do as one would be done by, and to love one's neighbor as oneself, constitute the ideal perfection of utilitarian morality. As the means of making the nearest approach to this ideal, utility would enjoin, first, that laws and social arrangements should place the happiness, or (as speaking practically it may be called) the interest, of every individual as nearly as possible in harmony with the interest of the whole; and secondly, that education and opinion, which have so fast a power over human character, should so use that power as to establish in the mind of every individual an indissoluble association between his own happiness and the good of the whole ... (*Utilitarianism*, p. 218)

We, and the world, would do well to follow Mill in these principles. All would be the better for it.

Mill aimed at the improvement of humankind. For this end, he was active in many causes. He denounced the take over by the British government of the East India Company, correctly anticipating the evils consequent upon the scramble for spoils by second rate English officials. He supported reform of the Irish land tenure system in order to relieve the poverty of the peasants. During his period in Parliament, he denounced English methods in Ireland, a move which was unfortunately denounced as support for the Fenians. In 1866 and 1867, he was active along with Herbert Spencer and many other liberals in the committee for the prosecution of Governor Eyre for atrocities in suppressing a rebellion by blacks in Jamaica. He supported attempts to preserve natural beauty and was a founder and strong supporter of the Commons Preservation Society.

In his own day Mill was immensely influential. He was never one to compromise his principles, and his pursuit of those ideals was steady and often successful.

Mill's metaphysics is perhaps less influential now than it was in his own day. Certainly, for many decades it stood in the shadow of idealism. His revival of formal logic inspired the developments that now date it. In the philosophy of science, his empiricism has for the most part stood the test of time. But his lasting influence has been in the areas of political and social philosophy. His defenses of utilitarianism and of liberty shaped the views of his own generation, and they continue to this to inspire

and to guide. In thought especially but also in action he made of the world a better place.

Bibliography

Mill's Works

The standard edition of Mill's writings, in thirty-three volumes, is the following:

CW Mill, J. S., *Collected Works of John Stuart Mill*, J. M. Robson (ed.), Toronto: University of Toronto Press, 1963ff.

The introductions by various authors are in each case worth reading. Volume and page numbers given below for Mill's works are to this edition. Page references in the preceding article refer to this edition.

(1838) "Bentham," CW, v. 10, pp. 75-115

(1840) "Coleridge," CW, v. 10. pp. 117-63

(1843) System of Logic, Ratiocinative and Inductive, CW, v. 7-8

(1848) Principles of Political Economy, CW, v. 2-3

(1859) On Liberty, CW, v. 18, pp. 213-310

(1861a) Utilitarianism, CW, v. 10, pp. 203-59

(1861b) Considerations on Representative Government, CW, v. 29, pp. 371-577

(1865a) An Examination of Sir William Hamilton's Philosophy, CW, 4. 9

(1865b) Auguste Comte and Positivism, CW, v. 10, pp. 261-368

(1869a) The Subjection of Women, CW, v. 21, pp. 259-340

(1869b) Notes to James Mill, *Analysis of the Phaenomena of the Human Mind*, 2nd edition, J. S. Mill (ed.); (1st edition, 1829; 2nd edition, London: Longman, Green, Reader and Dyer, 1869; reprinted New York: A. Keley, 1967)

(1873) Autobiography, CW, v. 1, pp. 1-290

(1874) Three Essays on Religion, CW, v. 10, pp. 369-489

Chapters on Socialism, CW, v. 5, pp. 703-53

(1963) Earlier Letters, CW, v. 12-13 [Mill's correspondence through 1848]

(1972) Later Letters, CW, v 14-16 [Mill's correspondence after 1848]

William Whewell

William Whewell (1794-1866) was one of the most important and influential figures in nineteenth-century Britain. Whewell, a polymath, wrote extensively on numerous subjects, including mechanics, mineralogy, geology, astronomy, political economy, theology, and architecture, as well as the works that remain the most well-known today in philosophy of science, history of science, and moral philosophy. He was one of the founding members and an early president of the British Association for the Advancement of Science, a fellow of the Royal Society, president of the Geological Society, and longtime Master of Trinity College, Cambridge. In his own time his influence was acknowledged by the major scientists of the day, such as John Herschel, Charles Darwin, Charles Lyell and Michael Faraday, who frequently turned to Whewell for philosophical and scientific advice, and, interestingly, for terminological assistance. Whewell invented the terms "anode," "cathode," and "ion" for Faraday. Upon the request of the poet Coleridge in 1833 Whewell invented the English word "scientist;" before this time the only terms in use were "natural philosopher" and "man of science."

Whewell is most known today for his massive works on the History and Philosophy of Science. His philosophy of science was attacked by John Stuart Mill in his *System of Logic*, causing an interesting and fruitful debate between them over the nature of inductive reasoning in science. It is in the context of this debate that Whewell's philosophy was rediscovered in the 20th century by critics of logical positivism. In this entry I will focus on the most important aspects of Whewell's works: his philosophy of science, including his views of induction, confirmation, and necessary truth; his view of the relation between scientific practice, history of science, and philosophy of science; and his moral philosophy. I will spend the most time on his view of induction, as this is the most interesting part of his philosophy as well as the most misinterpreted.

1. Biography

Whewell was born in 1794, the eldest child of a master-carpenter in Lancaster. The headmaster of his local grammar school, a parish priest, recognized Whewell's intellectual abilities and persuaded his father to allow him to attend the Haversham Grammar School in Westmoreland, some twelve miles to the north, where he would be able to qualify for a closed exhibition to Trinity College, Cambridge. In the 19th century and earlier, these "closed exhibitions" or scholarships were set aside for the children of working class parents, to allow for some social mobility. Whewell studied at Haversham Grammar for two years, and received private coaching in mathematics. Although he did win the exhibition it did not provide full resources for a boy of his family's means to attend Cambridge; so money had to be raised in a public subscription to supplement the scholarship money.

He thus came up to Trinity in 1812 as a "sub-sizar" (scholarship student). In 1814 he won the Chancellor's prize for his epic poem "Boadicea," thus following in the footsteps of his mother, who had published poems in the local papers. Yet he did not neglect the mathematical side of his training; in 1816 he proved his mathematical prowess by placing as both second Wrangler and second Smith's Prize man. The following year he won a college fellowship. He was elected to the Royal Society in 1820, and ordained a priest (as required for Trinity Fellows) in 1825. He took up the Chair in Mineralogy in 1828, and resigned it in 1832. In 1838 Whewell became Professor of Moral Philosophy. Almost immediately after his marriage to Cordelia Marshall on 12 October 1841, he was named Master of Trinity College upon the recommendation of the Prime Minister Robert Peel. He was Vice-Chancellor of the University in 1842 and again in 1855. In 1848 he played a large role in establishing the Natural and Moral Sciences Triposes at the University. His first wife died in 1855, and he remarried Lady Affleck, the sister of his friend Robert Ellis; Lady Affleck died in 1865. Whewell left no descendents when he died, after being thrown from his horse, on 6 March 1866.

2. Philosophy of Science: Induction

According to Whewell, all knowledge has both an ideal, or subjective dimension, as well as an objective dimension. He calls this the "fundamental antithesis" of knowledge. Whewell explains that "in every act of knowledge ... there are two opposite elements, which we may call Ideas and Perceptions" (1860a, p. 307). He criticizes Kant and the German Idealists for their exclusive focus on the ideal or subjective element, and Locke and the "Sensationalist School" for their exclusive focus on the empirical, objective element. Gaining knowledge, Whewell claims, requires attention to both elements, to ideas as well as sensations. These ideas, which he calls "Fundamental Ideas," are "supplied by the mind itself"--they are not (as Mill protests) merely received from our observations of the world. Whewell explains that the fundamental ideas are "not a consequence of experience, but a result of the particular constitution and activity of the mind, which is independent of all experience in its origin, though constantly combined with experience in its exercise" (1858a, I, p. 91). The mind is an active participant in our attempts to gain knowledge of the world, not merely a passive recipient of sense data. Ideas such as Space, Time, Cause,

and Resemblance provide a structure or form for the multitude of sensations we experience. The Ideas provide a structure by expressing the general relations that exist between our sensations (1847, I, p. 25). Thus, the Idea of Space allows us to apprehend objects as having form, magnitude, and position. Whewell holds then that observation is "idea-laden;" all observation, he says, involves "unconscious inference" using the fundamental ideas (see 1858a, I, p. 46). Each science has a particular fundamental idea which is needed to organize the facts with which that science is concerned; thus, Space is the fundamental idea of geometry, Cause the fundamental idea of mechanics, and Substance the fundamental idea of chemistry. Moreover, Whewell explains that each fundamental idea has certain "conceptions" included within it; these conceptions are "special modifications" of the idea applied to particular types of circumstances (1858b, p. 187). For example, the conception of force is a modification of the idea of Cause, applied to the particular case of motion (see 1858a, I, pp. 184-5 and p. 236).

Thus far, this discussion of the fundamental ideas may suggest that they are similar to Kant's forms of intuition, and indeed there are some similarities. Because of this, some commentators argue that Whewell's epistemology is a type of Kantianism (see, e.g., Butts, 1973, and Buchdahl, 1991). However, this interpretation ignores several crucial differences between the two views. The ideas of Space and Time do function in Whewell's epistemology as "conditions of experience" (1858a, I, p. 268), similar to Kant's forms of intuition. However, Whewell does not follow Kant in drawing a distinction between the forms of intuition, such as Space and Time, and the categories, or forms of thought, in which Kant includes Cause and Substance. Moreover, Whewell includes as fundamental ideas many which function not as conditions of experience but as conditions for having knowledge within their respective sciences: although it is certainly possible to have knowledge about the world without having a clear idea of Chemical Affinity, we could not have any knowledge of certain chemical processes within it. Unlike Kant, Whewell does not give an exhaustive list of fundamental ideas; indeed, he believes that others will emerge in the course of the development of new sciences. Further, the type of necessity which Whewell claims is derived from the ideas is very different from Kant's notion of the synthetic a priori. Finally, and perhaps most importantly, Whewell rejects Kant's subjectivism regarding the concepts of the understanding. The fundamental ideas, on Whewell's view, reflect objective features of the world, independent of the processes of the mind (I will return to these last two points in the section on Necessary Truth below).

I turn now to a discussion of the theory of induction Whewell develops with his antithetical epistemology. Whewell's first explicit, lengthy discussion of induction is found in his *Philosophy of the Inductive Sciences, founded upon their History*, which was originally published in 1840 (a second, enlarged edition appeared in 1847, and the third edition appeared as three separate works published between 1858 and 1860). Whewell considers himself to be a follower of Francis Bacon, claiming to be "renovating" Bacon's inductive method; thus one volume of the third edition of the *Philosophy* is entitled *Novum Organon Renovatum*. He calls his induction "Discoverers' Induction" and claims that it is used to discover both phenomenal and causal laws. Whewell follows Bacon in rejecting the standard, overly-narrow notion of induction that holds induction to be merely simple enumeration of instances. Rather, Whewell explains that, in induction, "there is a New Element added to the combination [of instances] by the very act of thought by which they were combined" (1847, II, p. 48). This "act of thought" is a process Whewell calls "colligation." Colligation, Whewell explains, is the mental operation of bringing together a

number of empirical facts by "superinducing" upon them a conception which unites the facts and renders them capable of being expressed by a general law. The conception thus provides the "true bond of Unity by which the phenomena are held together" (1847, II, p. 46), by providing a property shared by the known members of a class (in the case of causal laws, the colligating property is that of sharing the same cause).

Thus the known points of the Martian orbit were colligated by Kepler using the conception of an elliptical curve. Often new discoveries are made, Whewell points out, not when new facts are discovered but when the appropriate conception is applied to the facts. In the case of Kepler's discovery, the observed points of the orbit were known to Tycho Brahe, but only when Kepler applied the ellipse conception was the true path of the orbit discovered. Kepler was the first one to apply this conception to an orbital path in part because he had, in his mind, a very clear notion of the conception of an ellipse. This is important because the fundamental ideas and conceptions are provided by our minds, but they cannot be used in their innate form. Whewell explains that "the Ideas, the germs of them at least, were in the human mind before [experience]; but by the progress of scientific thought they are unfolded into clearness and distinctness" (1860a, p. 373). Whewell refers to this "unfolding" of ideas and conceptions as the "explication of conceptions." Explication is a necessary precondition to discovery, and it consists in a partly empirical, partly rational process. Scientists first try to clarify and make explicit a conception in their minds, then attempt to apply it to the facts they have precisely examined, to determine whether the conception can colligate the facts into a law. If not, the scientist uses this experience to attempt a further refinement of the conception. Whewell claims that a large part of the history of science is the "history of scientific ideas," that is, the history of their explication and subsequent use as colligating concepts. Thus in the case of Kepler's use of the ellipse conception, Whewell notes that "to supply this conception, required a special preparation, and a special activity in the mind of the discoverer. ... To discover such a connection, the mind must be conversant with certain relations of space, and with certain kinds of figures" (1849, pp. 28-9).

Once conceptions have been explicated, it is possible to choose the appropriate conception with which to colligate phenomena. But how is the appropriate conception chosen? According to Whewell , it is not a matter of guesswork. Nor, importantly, is it merely a matter of observation. Whewell explains that "there is a special process in the mind, in addition to the mere observation of facts, which is necessary" (1849, p. 40). This "special process in the mind" is a process of inference. "We infer more than we see," Whewell claims (1858a, I, p. 46). Typically, finding the appropriate conception with which to colligate a class of phenomena requires a series of inferences, thus Whewell claims that discoverers's induction is a process involving a "train of researches" (1857/1873, I, p. 297). He allows any type of inference in the colligation, including enumerative, eliminative and analogical. Thus Kepler in his *Astronomia Nova* (1609) can be seen as using various forms of inference to reach the ellipse conception (see Snyder, 1997a). When Augustus DeMorgan complains, in his 1847 logic text, about certain writers using the term "induction" as including "the use of the whole box of [logical] tools," he is undoubtedly referring to his teacher and friend Whewell.

After the known members of a class are colligated with the use of a conception, the second step of Whewell's discoverers' induction occurs: namely, the generalization of the shared property over the

complete class, including its unknown members. Often, as Whewell admits, this is a trivially simple procedure. Once Kepler supplied the conception of an ellipse to the observed members of the class of Mars' positions, he generalized it to all members of the class, including those which were unknown (unobserved), to reach the conclusion that "all the points of Mars' orbit lie on an ellipse with the sun at one focus." He then performed a further generalization to reach his first law of planetary motion: "the orbits of all the planets lie on ellipses with the sun at one focus."

I mentioned earlier that Whewell thought of himself as renovating Bacon's inductive philosophy. His inductivism does share numerous features with Bacon's method of interpreting nature: for instance the claims that induction must involve more than merely simple enumeration of instances, that science must be proceed by successive steps of generalization, that inductive science can reach unobservables (for Bacon, the "forms," for Whewell, unobservable entities such as light waves or properties such as elliptical orbits or gravitational forces). (For more on the relation between Whewell and Bacon see Snyder 1999). Yet, surprisingly, the received view of Whewell's methodology in the 20th century has tended to describe Whewell as an anti-inductivist in the Popperian mold (see, for example, Butts 1987, Buchdahl 1991, Laudan, 1980, Niiniluoto 1977, and Ruse 1975). That is, it is claimed that Whewell endorses a "conjectures and refutations" view of scientific discovery. However, it is clear from the above discussion that his view of discoverers' induction does not resemble the view asserting that hypotheses can be and are typically arrived at by mere guesswork. Moreover, Whewell explicitly rejects the hypothetico-deductive claim that hypotheses discovered by non-rational guesswork can be confirmed by consequentialist testing. For example, in his review of his friend Herschel's *Preliminary Discourse on the Study of Natural Philosophy*, Whewell argues, against Herschel, that verification is not possible when a hypothesis has been formed non-inductively (1831, pp. 400-1). Nearly thirty years later, in the last edition of the *Philosophy*, Whewell refers to the belief that "the discovery of laws and causes of phenomena is a loose hap-hazard sort of guessing," and claims that this type of view "appears to me to be a misapprehension of the whole nature of science" (1860a, p. 274). In other mature works he notes that discoveries are made "not by any capricious conjecture of arbitrary selection" (1858a, I, p. 29) and explains that new hypotheses are properly "collected from the facts" (1849, p. 17).

Why has Whewell been misinterpreted by so many commentators? One reason has to do with the error of reading certain terms used by Whewell in the 19th century as if they held the same meaning they have in the 20th and 21st. Thus, since Whewell does at times speak of "conjectures" and "guesses," we are told that he shares Popper's methodology. He speaks, for instance, of the "happy guesses" made by scientists (1858b, p. 64) and claims that "advances in knowledge" often follow "the previous exercise of some boldness and license in guessing" (1847, II, p. 55). But Whewell often uses these terms in a way which connotes a conclusion which is simply not conclusively confirmed. The *Oxford English Dictionary* tells us that prior to the 20th century the term "conjecture" was used to connote not a hypothesis reached by non-rational means, but rather one which is "unverified," or which is "a conclusion as to what is likely or probable" (as opposed to the results of demonstration). The term is used this way by Bacon, Kepler, Newton, and Dugald Stewart, writers whose work was well-known to Whewell. In other places where Whewell uses the term "conjecture" he suggests that what appears to be the result of guesswork is actually what we might call an "educated guess," i.e., a conclusion drawn by (weak) inference. Whewell describes Kepler's discovery, which seems so "capricious and fanciful" as actually being "regulated" by

his "clear scientific ideas" (1857/1873, I, pp. 291-2). Finally Whewell's use of the terminology of guessing sometimes occurs in the context of a distinction he draws between the generation of a number of possible conceptions, and the selection of one to superinduce upon the facts. Before the appropriate conception is found, the scientist must be able to call up in his mind a number of possible ones (see 1858b, p. 79). Whewell notes that this calling up of many possibilities "is, in some measure, a process of conjecture." However, selecting the appropriate conception with which to colligate the data is not conjectural (1858b, p. 78). Thus Whewell claims that the selection of the conception is often "*preluded* by guesses" (1858b, p. xix); he does not, that is, claim that the selection *consists* in guesswork. When inference is not used to select the appropriate conception, the resulting theory is not an "induction," but rather a "hasty and imperfect hypothesis." He draws such a distinction between Copernicus' heliocentric theory, which he calls an induction, and the heliocentric system proposed by Aristarchus in the third century b.c., to which he refers as a hasty and imperfect hypothesis (1857/1873, I, p. 258).

Thus Whewell's philosophy of science cannot be described as the hypothetico-deductive view. It is an inductive method; yet it clearly differs from the more narrow inductivism of Mill. Whewell's view of induction has the advantage over Mill's of allowing the inference to unobservable properties and entities (for more on this topic see Snyder 1997a and 1997b).

3. Philosophy of Science: Confirmation

On Whewell's view, once a theory is invented by discoverers' induction, it must pass a variety of deductive tests before it can be considered confirmed as an empirical truth. These tests are prediction, consilience, and coherence (see 1858b, pp. 83-96). These are characterized by Whewell as, first, that "our hypotheses ought to *fortel* [sic] phenomena which have not yet been observed" (1858b, p. 86); second, that they should "explain and determine cases of a *kind different* from those which were contemplated in the formation" of those hypotheses (1858b, p. 88); and third that hypotheses must "become more coherent" over time (1858b, p. 91).

I start by discussing the criterion of prediction. Our hypotheses ought to foretell phenomena, "at least all phenomena of the same kind," Whewell explains, because "our assent to the hypothesis implies that it is held to be true of all particular instances. That these cases belong to past or to future times, that they have or have not already occurred, makes no difference in the applicability of the rule to them. Because the rule prevails, it includes all cases" (1858b, p. 86). Whewell's point here is simply that since our hypotheses are in universal form, a true hypothesis will cover all particular instances of the rule, including past, present, and future cases. But he also makes the stronger claim that successful predictions of unknown facts provide greater confirmatory value than explanations of already-known facts. Thus he holds the historical claim that "new evidence" is more valuable than "old evidence." He argues that "to predict unknown facts found afterwards to be true is ... a confirmation of a theory which in impressiveness and value goes beyond any explanation of known facts" (1857/1873, II, p. 557). Whewell claims that the agreement of the prediction with what occurs (i.e., the fact that the prediction turns out to be correct), is "nothing strange, if the theory be true, but quite unaccountable, if it be not" (1860a, pp. 273-4). For example, if Newtonian theory were not true, he argues, the fact that from the theory we could

correctly predict the existence, location and mass of a new planet, Neptune (as did happen in 1846), would be bewildering, and indeed miraculous.

An even more valuable confirmation criterion, according to Whewell, is that of "consilience." Whewell explains that "the evidence in favour of our induction is of a much higher and more forcible character when it enables us to explain and determine [i.e., predict] cases of a *kind different* from those which were contemplated in the formation of our hypothesis. The instances in which this have occurred, indeed, impress us with a conviction that the truth of our hypothesis is certain" (1858b, pp. 87-8). Whewell calls this type of evidence a "jumping together" or "consilience" of inductions. An induction, which results from the colligation of one class of facts, is found also to colligate successfully facts belonging to another class. This is especially powerful as confirmation when the second class of phenomena had appeared to be unrelated to the first. For instance, consilience occurred when "the force of Universal Gravitation, which had been inferred from the Perturbations of the moon and planets by the sun and by each other, also accounted for the fact, apparently altogether dissimilar and remote, of the *Precession of the equinoxes*" (1847, II, p. 66).

Whewell discusses a further, related test of a theory's truth: namely, "coherence." In the case of true theories, Whewell claims, "the system becomes more coherent as it is further extended. The elements which we require for explaining a new class of facts are already contained in our system....In false theories, the contrary is the case" (1858b, p. 91). Coherence occurs when we are able to extend our hypothesis to colligate a new class of phenomena without ad hoc modification of the hypothesis. When Newton extended his theory regarding an inverse-square attractive force, which colligated facts of planetary motion and lunar motion, to the class of "tidal activity," he did not need to add any new suppositions to the theory in order to colligate correctly the facts about particular tides. On the other hand, Whewell claims, when phlogiston theory, which colligated facts about the class of phenomena "chemical combination," was extended to colligate the class of phenomena "weight of bodies," it was *unable* to do so without an ad hoc and implausible modification (namely, the assumption that phlogiston has "negative weight") (see 1858b, pp. 92-3). Thus coherence can be seen as a type of consilience that happens over time; indeed, Whewell remarks that these two criteria--consilience and coherence--"are, in fact, hardly different" (1858b, p. 95).

4. Philosophy of Science: Necessary Truth

A particularly intriguing aspect of Whewell's philosophy of science is his claim that empirical science can reach necessary truths. Explaining this apparently contradictory claim was considered by Whewell and Herschel to be the "ultimate problem" of philosophy (see Morrison 1997). Whewell explains it by reference to his antithetical epistemology. Necessary truths are truths which can be known a priori; they can be known in this way because they are necessary consequences of ideas which are a priori. They are necessary consequences in the sense of being analytic consequences; Whewell explicitly rejects Kant's claim that necessary truths are synthetic. Using the example "7 + 8 = 15," Whewell claims that "we refer to our conceptions of seven, of eight, and of addition, and as soon as we possess the conceptions distinctly, we see that the sum must be 15." Merely by knowing the *meanings* of "seven," and "eight," and

"addition," we see that it follows necessarily that "7 + 8 = 15" (1848, p. 471).

Once the Ideas and conceptions are explicated, so that we understand their meanings, the necessary truths which follow from them are seen as being necessarily true. Thus, once the Idea of Space is explicated, it is seen to be necessarily true that "two straight lines cannot enclose a space." Whewell suggests that the first law of motion is also a necessary truth, which was knowable a priori once the idea of Cause and the associated conception of force were explicated. This is why empirical science is needed to see necessary truths—because, as we saw above, empirical science is needed in order to explicate the ideas. Thus Whewell also claims that, in the course of science, truths which at first required experiment to be known are seen to be capable of being known independently of experiment. That is, once the idea is clarified, the necessary connection between the idea and an empirical truth becomes apparent. Whewell claims that "though the discovery of the First Law of Motion was made, historically speaking, by means of experiment, we have now attained a point of view in which we see that it might have been certainly known to be true independently of experience" (1847, I, p. 221). Science, then, consists in the "idealization of facts," the transferring of truths from the empirical to the ideal side of the fundamental antithesis. He describes this by noting that there is a "progressive intuition of necessary truths."

Although they follow analytically from the meanings of ideas our minds supply, necessary truths are nevertheless informative statements about the physical world outside us; they have empirical content. Whewell's justification for this claim is a theological one. Whewell notes that God created the universe in accordance with certain "Divine Ideas." That is, all objects and events in the world were created by God to conform to certain of his ideas. For example, God made the world such that it corresponds to the idea of Cause partially expressed by the axiom "every event has a cause." Hence in the universe every event conforms to this idea, not only by having a cause but by being such that it could not occur without a cause. On Whewell's view, we are able to have knowledge of the world because the fundamental ideas which are used to organize our sciences resemble the ideas used by God in his creation of the physical world. The fact that this is so is no coincidence: God has created our minds such that they contain these same ideas. That is, God has given us our ideas so that "they can and must agree with the world" (1860a, p. 359). God intends that we can have knowledge of the physical world, and this is possible only through the use of ideas which resemble those that were used in creating the world. Hence with our ideas we can colligate correctly the facts of the world and form true theories. And when these ideas are distinct, we can know a priori the axioms which express their meaning.

An interesting consequence of this interpretation of Whewell's view of necessity is that every law of nature is a necessary truth, in virtue of following analytically from some idea used by God in creating the world. Whewell draws no distinction between truths which can be idealized and those which cannot; thus, potentially, any empirical truth can be seen to be a necessary truth, once the ideas and conceptions are explicated sufficiently. For example, Whewell suggests that experiential truths such as "salt is soluble" may be necessary truths, even if we do not recognize this necessity (i.e., even if it is not yet knowable a priori): (1860b, p. 483). Whewell's view thus destroys the line traditionally drawn between laws of nature and the axiomatic propositions of the pure sciences of mathematics; mathematical truth is granted no special status.

Whewell thus suggests a view of scientific understanding which is, not surprisingly, grounded in his conception of natural theology. Since our ideas are "shadows" of the Divine Ideas, to see a law as a necessary consequence of our ideas is to see it as a consequence of the Divine Ideas exemplified in the world. Understanding involves seeing a law as being not an arbitrary "accident on the cosmic scale," but as a necessary consequence of the ideas God used in creating the universe. Hence the more we idealize the facts, the more difficult it will be to deny God's existence. We will come to see more and more truths as the intelligible result of intentional design. This view is related to the claim Whewell makes in his Bridgewater Treatise (1833), that the more we study the laws of nature the more convinced we will be in the existence of a Divine Law-giver

5. Relation of Science to Philosophy of Science

An issue of interest to philosophers of science today is the relation between knowledge of the actual practice and history of science and writing philosophy of science. Whewell is interesting to examine in relation to this issue because he claimed to be inferring his philosophy of science from his study of the history and practice of science. His large-scale *History of the Inductive Sciences* (first edition published 1837) was a survey of science from ancient to modern times. Besides knowing about science by studying its history, Whewell had first-hand knowledge: he was actively involved in science in several important ways. In 1825 he traveled to Berlin, Freiburg and Vienna to study mineralogy and crystallography with Mohs and other acknowledged masters of the field (see Becher, 1986). He published numerous papers in the field, as well as a monograph, and is still credited with making important contributions to giving a mathematical foundation to crystallography. He also made contributions to the science of tidal research, pushing for a large-scale world-wide project of tidal observations; he won a Royal Society gold medal for this accomplishment (see Ruse, 1991). Whewell acted as a terminological consultant for Faraday and other scientists, who wrote to him asking for new words. Whewell only provides terminology when he feels he is fully knowledgeable about the science involved. In his section on the "Language of Science" in the *Philosophy*, Whewell makes clear this position (see 1858b, p. 293). Another interesting aspect of his intercourse with scientists becomes clear in reading his correspondence with them: namely, that Whewell constantly pushes Faraday, Forbes, Lubbock and others to perform certain experiments, make specific observations, and to try to connect their findings in ways of interest to Whewell (see Whewell Papers). In all these ways, Whewell indicates that he has a deep understanding of the activity of science.

So how is this important for his work on the philosophy of science? Some commentators have claimed that Whewell developed an a priori philosophy of science and then shaped his *History* to conform to his own view (see Stoll 1929 and Strong 1955). It is true that he starts out, from his undergraduate days, with the project of reforming the inductive philosophy of Bacon; indeed this early inductivism leads him to the view that learning about scientific method must be inductive (i.e., that it requires the study of the history of science). Yet he also refuses to complete his *Philosophy* before he has written the *History*; he even sends proof-sheets of the *History* to his many scientist-friends to ensure the accuracy of his account. Ultimately, he criticizes Mill's view of induction developed in the *System of Logic* on the grounds that Mill has not found a large number of appropriate examples illustrating the use of his "Methods of Experimental Inquiry." Thus it appears that what is important to Whewell is not whether a philosophy of

science is, in fact, inferred from a study of the history of science, but rather, whether a philosophy of science is *inferable from* it. That is, regardless of how a philosopher came to invent her theory, she must be able to show it to be exemplified in the actual scientific practice used throughout history.

6. Moral Philosophy

Whewell's moral philosophy was criticized by Mill as being "intuitionist" (see Mill, 1852). Mill meant two claims about his moral philosophy by the use of this term. The first characteristic of an intuitionist morality is the claim that there are primary principles of morality which are known by intuition. Whewell does claim this, but what he means by "intuition" is not the non-rational process of which Mill accuses him. For Whewell the contemplation of moral principles is a rational process; thus he refers to moral rules as "principles of reason" (1864, p. 3), and describes the discovery of these rules as an activity of reason (1864, pp. 23-4). Unlike other intuitionist moral philosophers, Whewell holds that intuition plays only a small role in our moral decision-making; reason leads to common decisions about the correct way to act (see 1864, p. 43). Thus his position is more accurately described as a form of rationalism, or "rational intuitionism," in the sense later used by Rawls (see Singer, 1992).

The second central aspect of intuitionism is the claim that moral rules are necessary truths which are self-evident. This is often taken, as it is by Mill, to lead to the conclusion that there can be no progress in morality—what is self-evident must always remain so—and thus to the further conclusion that the intuitionist considers the current rules of society to be necessary truths. Such a view would tend to support the status quo, as Mill rightly complains. (Thus he accuses Whewell of justifying evil practices such as slavery, forced marriages, and cruelty to animals.) But Mill is wrong to attribute such a view to Whewell. Whewell does claim that moral rules are necessary truths, and invests them with the epistemological status of self-evident "axioms" (see 1864, p. 58). However, as noted above, Whewell's view of necessary truth is a progressive one. The realm of morality, like the realm of physical science, is structured by certain Fundamental Ideas: Benevolence, Justice, Truth, Purity, and Order (see 1852, p. xxiii). These moral ideas are conditions of our moral experience; they enable us to perceive actions as being in accordance with the demands of morality. Like the ideas of the physical sciences, the ideas of morality must be explicated before the moral rules can be derived from them (see 1860a, p. 388). There is a progressive intuition of necessary truth in morality as well as in science. Hence it does not follow that because the moral truths are axiomatic and self-evident that we currently know them (see 1846, pp. 38-9). Whewell thus claims that "to test self-evidence by the casual opinion of individual men, is a self-contradiction" (1846, p. 35). Nevertheless, Whewell does claim that we can look to the dictates of positive law of the most morally advanced societies as a starting point in our explication of the moral ideas. But he is not therefore suggesting that these laws are the standard of morality. Just as we examine the phenomena of the physical world in order to explicate our scientific conceptions, we can examine the facts of positive law and the history of moral philosophy in order to explicate our moral conceptions. Mill is therefore wrong to interpret Whewell's moral philosophy as a justification of the status quo or as constituting a "vicious circle." Rather, Whewell's view shares some features of Rawls's later use of the notion of "reflective equilibrium."

Bibliography

Whewell's letters and papers, mostly unpublished, are found in the Whewell Collection, Trinity College Library, Cambridge. A selection of letters was published by I. Todhunter in *William Whewell, An account of his Writings*, Vol. II (London, 1876) and by J. Stair-Douglas in *The Life, and Selections from the Correspondence of William Whewell* (London, 1882).

During his lifetime Whewell published approximately 150 books, articles, scientific papers, society reports, reviews, and translations. In the list which follows I mention only his most important philosophical works. More complete bibliographies can be found in Yeo (1993) and Fisch and Schaffer (1991).

Major Philosophical Works by Whewell

- (1831) "Review of J. Herschel's *Preliminary Discourse on the Study of Natural Philosophy (1830)," Quarterly Review 90*: 374-407.
- (1833) *Astronomy and General Physics Considered With Reference to Natural Theology* (Bridgewater Treatise), Cambridge.
- (1840) *The Philosophy of the Inductive Sciences, Founded Upon Their History*, in two volumes, London.
- (1844) "On the Fundamental Antithesis of Philosophy," Transactions of the Cambridge Philosophical Society 7, part 2, 170-81.
- (1845) *The Elements of Morality, including Polity*, in two volumes, London.
- (1846) *Lectures on Systematic Morality*, London.
- (1847) *The Philosophy of the Inductive Sciences, Founded Upon Their History*, 2nd edition, in two volumes, London.
- (1848) "Second Memoir on the Fundamental Antithesis of Philosophy," *Transactions of the Cambridge Philosophical Society* 8, part five, pp. 614-20.
- (1849) *Of Induction, With Especial Reference to Mr. J. Stuart Mill's System of Logic*, London.
- (1850) "Mathematical Exposition of Some Doctrines of Political Economy: Second Memoir," *Transactions of the Cambridge Philosophical Society* 9:128-49.
- (1853) *Of the Plurality of Worlds. An Essay*, London.
- (1857) "Spedding's Complete Edition of the Works of Bacon," *Edinburgh Review* 106:287-322.
- (1857/1873) *History of the Inductive Sciences, from the Earliest to the Present Time*, 3rd edition, in two volumes, New York.
- (1858a) *The History of Scientific Ideas*, in two volumes, London.
- (1858b) *Novum Organon Renovatum*, London.
- (1860a) *On the Philosophy of Discovery: Chapters Historical and Critical*, London.
- (1860b) "Remarks on a Review of the Philosophy of the Inductive Sciences," letter to John Herschel, 11 April 1844; published as essay F in 1860a.
- (1861) Plato's *Republic* (translation). Cambridge.
- (1862) *Six Lectures on Political Economy*, Cambridge.

- (1864) *The Elements of Morality, Including Polity*. 4th edition, with Supplement, Cambridge.
- (1866a) "Comte and Positivism," *Macmillan's Magazine* 13:353-62.
- (1866b) "Grote's Plato," *Fraser's Magazine* 73:411-23.

Sir Karl Popper (1902-1994)

Karl Popper

Karl Popper is generally regarded as one of the greatest philosophers of science of this century. He was also a social and political philosopher of considerable stature, a self-professed ‘critical-rationalist’, a dedicated opponent of all forms of scepticism, conventionalism, and relativism in science and in human affairs generally, a committed advocate and staunch defender of the ‘Open Society’, and an implacable critic of totalitarianism in all of its forms. One of the many remarkable features of Popper's thought is the scope of his intellectual influence. In the modern technological and highly-specialised world scientists are rarely aware of the work of philosophers; it is virtually unprecedented to find them queuing up, as they have done in Popper's case, to testify to the enormously practical beneficial impact which that philosophical work has had upon their own. But notwithstanding the fact that he wrote on even the most technical matters with consummate clarity, the scope of Popper's work is such that it is commonplace by now to find that commentators tend to deal with the epistemological, scientific and social elements of his thought as if they were quite disparate and unconnected, and thus the fundamental unity of his philosophical vision and method has to a large degree been dissipated. Here we will try to trace the threads which interconnect the various elements of his philosophy, and which give it its fundamental

unity.

Section Headings:

Life

Karl Raimund Popper was born on 28 July 1902 in Vienna, which at that time could make some claim to be the cultural epicentre of the western world. His parents, who were of Jewish origin, brought him up in an atmosphere which he was later to describe as ‘decidedly bookish’. His father was a lawyer by profession, but he also took a keen interest in the classics and in philosophy, and communicated to his son an interest in social and political issues which he was to never lose. His mother inculcated in him such a passion for music that for a time he seriously contemplated taking it up as a career, and indeed he initially chose the history of music as a second subject for his Ph.D examination. Subsequently, his love for music became one of the inspirational forces in the development of his thought, and manifested itself in his highly original interpretation of the relationship between dogmatic and critical thinking, in his account of the distinction between objectivity and subjectivity, and, most importantly, in the growth of his hostility towards all forms of historicism, including historicist ideas about the nature of the ‘progressive’ in music. The young Karl attended the local *Realgymnasium*, where he was unhappy with the standards of the teaching, and, after an illness which kept him at home for a number of months, he left to attend the University of Vienna in 1918. However, he did not formally enrol at the University by taking the matriculation examination for another four years. 1919 was in many respects the most important formative year of his intellectual life. In that year he became heavily involved in left-wing politics, joined the Association of Socialist School Students, and became for a time a Marxist. However, he was quickly disillusioned with the doctrinaire character of the latter, and soon abandoned it entirely. He also discovered the psychoanalytic theories of Freud and Adler (under whose aegis he engaged

briefly in social work with deprived children), and listened entranced to a lecture which Einstein gave in Vienna on relativity theory. The dominance of the critical spirit in Einstein, and its total absence in Marx, Freud and Adler, struck Popper as being of fundamental importance: the latter, he came to think, couched their theories in terms which made them amenable only to confirmation, while Einstein's theory, crucially, had testable implications which, if false, would have falsified the theory itself.

Popper obtained a primary school teaching diploma in 1925, took a Ph.D. in philosophy in 1928, and qualified to teach mathematics and physics in secondary school in 1929. The dominant philosophical group in Vienna from its inception in 1928 was the *Wiener Kreis*, the circle of ‘scientifically-minded’ intellectuals who gathered around the figure of Moritz Schlick. This included Rudolf Carnap, Otto Neurath, Viktor Kraft, Hans Hahn, and Herbert Feigl. The principal objective of the members of the Circle was to unify the sciences, which carried with it, in their view, the need to eliminate metaphysics once and for all by showing that metaphysical propositions are meaningless. Thus was born the movement in philosophy known as logical positivism, and its chief tool became the verification principle. Although he was friendly with some of the Circle's members - especially Feigl, who encouraged him to write his first book - and shared their esteem for science, Popper was heavily critical of the main tenets of logical positivism, especially of what he considered to be its misplaced focus on the theory of meaning in philosophy and upon verification in scientific methodology. He articulated his own view of science, and his criticisms of the positivists, in his first work, published under the title *Logik der Forschung* in 1934. The book - which he was later to claim rang the death knell for logical positivism - attracted more attention than Popper had anticipated, and he was invited to lecture in England in 1935. He spent the next few years working productively on science and philosophy, but storm clouds were gathering - the growth of Nazism in Germany and Austria compelled him, like many other intellectuals who shared his Jewish origins, to leave his native country.

In 1937 Popper took up a position teaching philosophy at the University of Canterbury in New Zealand, where he was to remain for the duration of the Second World War. The annexation of Austria in 1938 became the catalyst which prompted him to refocus his writings on social and political philosophy. In 1946 he moved to England to teach at the London School of Economics, and became professor of logic and scientific method at the University of London in 1949. From this point on Popper's reputation and stature as a philosopher of science and social thinker grew enormously, and he continued to write prolifically - a number of his works, particularly *The Logic of Scientific Discovery* (1959), are now universally recognised as classics in the field. He was knighted in 1965, and retired from the University of London in 1969, though he remained active as a writer, broadcaster and lecturer until his death in 1994. (For more detail on Popper's life, cf. his *Unended Quest*).

Backdrop to his Thought

A number of biographical features may be identified as having a particular influence upon Popper's thought. In the first place, his teenage flirtation with Marxism left him thoroughly familiar with the Marxist view of economics, class-war, and history. Secondly, he was appalled by the failure of the

democratic parties to stem the rising tide of fascism in his native Austria in the 1920s and 1930s, and the effective welcome extended to it by the Marxists. The latter acted on the ideological grounds that it constituted what they believed to be a necessary dialectical step towards the implosion of capitalism and the ultimate revolutionary victory of communism. This was one factor which led to the much feared *Anschluss*, the annexation of Austria by the German Reich, the anticipation of which forced Popper into permanent exile from his native country. *The Poverty of Historicism* (1944) and *The Open Society and Its Enemies* (1945), his most impassioned and brilliant social works, are as a consequence a powerful defence of democratic liberalism as a social and political philosophy, and a devastating critique of the principal philosophical presuppositions underpinning all forms of totalitarianism. Thirdly, as we have seen, Popper was profoundly impressed by the differences between the allegedly ‘scientific’ theories of Freud and Adler and the revolution effected by Einstein's theory of relativity in physics in the first two decades of this century. The main difference between them, as Popper saw it, was that while Einstein's theory was highly ‘risky’, in the sense that it was possible to deduce consequences from it which were, in the light of the then dominant Newtonian physics, highly improbable (e.g. that light is deflected towards solid bodies - confirmed by Eddington's experiments in 1919), and which would, if they turned out to be false, falsify the whole theory, nothing could, even *in principle*, falsify psychoanalytic theories. These latter, Popper came to feel, have more in common with primitive myths than with genuine science. That is to say, he saw that what is apparently the chief source of strength of psychoanalysis, and the principal basis on which its claim to scientific status is grounded, viz. its capability to accommodate, and explain, every possible form of human behaviour, is in fact a critical weakness, for it entails that it is not, and could not be, genuinely predictive. Psychoanalytic theories by their nature are insufficiently precise to have negative implications, and so are immunised from experiential falsification.

The Marxist account of history too, Popper held, is not scientific, although it differs in certain crucial respects from psychoanalysis. For Marxism, Popper believed, had been initially scientific, in that Marx had postulated a theory which was genuinely predictive. However, when these predictions were not in fact borne out, the theory was saved from falsification by the addition of *ad hoc* hypotheses which made it compatible with the facts. By this means, Popper asserted, a theory which was initially genuinely scientific degenerated into pseudo-scientific dogma.

These factors combined to make Popper take *falsifiability* as his criterion for demarcating science from non-science: if a theory is incompatible with possible empirical observations it is scientific; conversely, a theory which is compatible with all such observations, either because, as in the case of Marxism, it has been modified solely to accommodate such observations, or because, as in the case of psychoanalytic theories, it is consistent with all possible observations, is unscientific. For Popper, however, to assert that a theory is unscientific, is not necessarily to hold that it is unenlightening, still less that it is meaningless, for it sometimes happens that a theory which is unscientific (because it is unfalsifiable) at a given time may become falsifiable, and thus scientific, with the development of technology, or with the further articulation and refinement of the theory. Further, even purely mythogenic explanations have performed a valuable function in the past in expediting our understanding of the nature of reality.

The Problem of Demarcation

As Popper represents it, the central problem in the philosophy of science is that of demarcation, i.e. of distinguishing between science and what he terms 'non-science', under which heading he ranks, amongst others, logic, metaphysics, psychoanalysis, and Adler's individual psychology. Popper is unusual amongst contemporary philosophers in that he *accepts* the validity of the Humean critique of induction, and indeed, goes beyond it in arguing that induction is never actually used by the scientist. However, he does not concede that this entails the scepticism which is associated with Hume, and argues that the Baconian/Newtonian insistence on the primacy of 'pure' observation, as the initial step in the formation of theories, is completely misguided: all observation is selective and theory-laden - there are no pure or theory-free observations. In this way he destabilises the traditional view that science can be distinguished from non-science on the basis of its inductive methodology; in contradistinction to this, Popper holds that there is no unique methodology specific to science. Science, like virtually every other human, and indeed organic, activity, Popper believes, consists largely of problem-solving.

Popper, then, repudiates induction, and rejects the view that it is the characteristic method of scientific investigation and inference, and substitutes *falsifiability* in its place. It is easy, he argues, to obtain evidence in favour of virtually any theory, and he consequently holds that such 'corroboration', as he terms it, should count scientifically only if it is the positive result of a genuinely 'risky' prediction, which might conceivably have been false. For Popper, a theory is scientific only if it is refutable by a conceivable event. Every genuine test of a scientific theory, then, is logically an attempt to refute or to falsify it, and one genuine counter-instance falsifies the whole theory. In a critical sense, Popper's theory of demarcation is based upon his perception of the logical asymmetry which holds between verification and falsification: it is logically impossible to conclusively verify a universal proposition by reference to experience (as Hume saw clearly), but a single counter-instance conclusively falsifies the corresponding universal law. In a word, an exception, far from 'proving' a rule, conclusively refutes it.

Every genuine scientific theory then, in Popper's view, is *prohibitive*, in the sense that it forbids, by implication, particular events or occurrences. As such it can be tested and falsified, but never logically verified. Thus Popper stresses that it should not be inferred from the fact that a theory has withstood the most rigorous testing, for however long a period of time, that it has been verified; rather we should recognise that such a theory has received a high measure of corroboration. and may be provisionally retained as the best available theory until it is finally falsified (if indeed it is ever falsified), and/or is superseded by a better theory.

Popper has always drawn a clear distinction between the *logic* of falsifiability and its *applied methodology*. The logic of his theory is utterly simple: if a single ferrous metal is unaffected by a magnetic field it cannot be the case that all ferrous metals are affected by magnetic fields. Logically speaking, a scientific law is conclusively falsifiable although it is not conclusively verifiable. Methodologically, however, the situation is much more complex: no observation is free from the possibility of error - consequently we may question whether our experimental result was what it appeared to be.

Thus, while advocating falsifiability as the criterion of demarcation for science, Popper explicitly allows for the fact that in practice a single conflicting or counter-instance is never sufficient methodologically to falsify a theory, and that scientific theories are often retained even though much of the available evidence conflicts with them, or is anomalous with respect to them. Scientific theories may, and do, arise genetically in many different ways, and the manner in which a particular scientist comes to formulate a particular theory may be of biographical interest, but it is of no consequence as far as the philosophy of science is concerned. Popper stresses in particular that there is no unique way, no single method such as induction, which functions as the route to scientific theory, a view which Einstein personally endorsed with his affirmation that ‘There is no logical path leading to [the highly universal laws of science]. They can only be reached by intuition, based upon something like an intellectual love of the objects of experience’. Science, in Popper's view, starts with problems rather than with observations - it is, indeed, precisely in the context of grappling with a problem that the scientist makes observations in the first instance: his observations are selectively designed to test the extent to which a given theory functions as a satisfactory solution to a given problem.

On this criterion of demarcation physics, chemistry, and (non-introspective) psychology, amongst others, are sciences, psychoanalysis is a pre-science (i.e. it undoubtedly contains useful and informative truths, but until such time as psychoanalytical theories can be formulated in such a manner as to be falsifiable, they will not attain the status of scientific theories), and astrology and phrenology are pseudo-sciences. Formally, then, Popper's theory of demarcation may be articulated as follows: where a ‘basic statement’ is to be understood as a particular observation-report, then we may say that a theory is scientific if and only if it divides the class of basic statements into the following two non-empty sub-classes: (a) the class of all those basic statements with which it is inconsistent, or which it prohibits - this is the class of its *potential falsifiers* (i.e. those statements which, if true, falsify the whole theory), and (b) the class of those basic statements with which it is consistent, or which it permits (i.e. those statements which, if true, corroborate it, or bear it out).

The Growth of Human Knowledge

For Popper accordingly, the growth of human knowledge proceeds from our problems and from our attempts to solve them. These attempts involve the formulation of theories which, if they are to explain anomalies which exist with respect to earlier theories, must go beyond existing knowledge and therefore require a leap of the imagination. For this reason, Popper places special emphasis on the role played by the independent creative imagination in the formulation of theory. The centrality and priority of *problems* in Popper's account of science is paramount, and it is this which leads him to characterise scientists as ‘problem-solvers’. Further, since the scientist begins with problems rather than with observations or ‘bare facts’, Popper argues that the only logical technique which is an integral part of scientific method is that of the deductive testing of theories which are not themselves the product of any logical operation. In this deductive procedure conclusions are inferred from a tentative hypothesis. These conclusions are then compared with one another and with other relevant statements to determine whether they falsify or

corroborate the hypothesis. Such conclusions are not directly compared with the facts, Popper stresses, simply because there are no ‘pure’ facts available; all observation-statements are theory-laden, and are as much a function of purely subjective factors (interests, expectations, wishes, etc.) as they are a function of what is objectively real.

How then does the deductive procedure work? Popper specifies four steps:

> (a) The first is *formal,* a testing of the internal consistency of the theoretical system to see if it involves any contradictions.
>
> (b) The second step is *semi-formal,* the axiomatising of the theory to distinguish between its empirical and its logical elements. In performing this step the scientist makes the logical form of the theory explicit. Failure to do this can lead to category-mistakes - the scientist ends up asking the wrong questions, and searches for empirical data where none are available. Most scientific theories contain analytic (i.e. *a priori*) and synthetic elements, and it is necessary to axiomatise them in order to distinguish the two clearly.
>
> (c) The third step is the comparing of the new theory with existing ones to determine whether it constitutes an advance upon them. If it does not constitute such an advance, it will not be adopted. If, on the other hand, its explanatory success matches that of the existing theories, and additionally, it explains some hitherto anomalous phenomenon, or solves some hitherto unsolvable problems, it will be deemed to constitute an advance upon the existing theories, and will be adopted. Thus science involves theoretical progress. However, Popper stresses that we ascertain whether one theory is better than another by deductively testing both theories, rather than by induction. For this reason, he argues that a theory is deemed to be better than another if (while unfalsified) it has greater empirical content, and therefore greater predictive power than its rival. The classic illustration of this in physics was the replacement of Newton's theory of universal gravitation by Einstein's theory of relativity. This elucidates the nature of science as Popper sees it: at any given time there will be a number of conflicting theories or conjectures, some of which will explain more than others. The latter will consequently be provisionally adopted. In short, for Popper any theory X is better than a ‘rival’ theory Y if X has *greater empirical content*, and hence *greater predictive power*, than Y.
>
> (d) The fourth and final step is the testing of a theory by the empirical application of the conclusions derived from it. If such conclusions are shown to be true, the theory is corroborated (but never verified). If the conclusion is shown to be false, then this is taken as a signal that the theory cannot be completely correct (logically the theory is falsified), and the scientist begins his quest for a better theory. He does not, however, *abandon* the present theory until such time as he has a better one to substitute for it. More precisely, the method of theory-testing is as follows: certain singular propositions are deduced from the new theory - these are predictions, and of special interest are those predictions which are

> 'risky' (in the sense of being intuitively implausible or of being startlingly novel) and experimentally testable. From amongst the latter the scientist next selects those which are not derivable from the current or existing theory - of particular importance are those which contradict the current or existing theory. He then seeks a decision as regards these and other derived statements by comparing them with the results of practical applications and experimentation. If the new predictions are borne out, then the new theory is *corroborated* (and the old one falsified), and is adopted as a working hypothesis. If the predictions are not borne out, then they falsify the theory from which they are derived. Thus Popper retains an element of empiricism: for him scientific method does involve making an appeal to experience. But unlike traditional empiricists, Popper holds that experience cannot *determine* theory (i.e. we do not argue or infer from observation to theory), it rather *delimits* it: it shows which theories are false, not which theories are true. Moreover, Popper also rejects the empiricist doctrine that empirical observations are, or can be, infallible, in view of the fact that they are themselves theory-laden.

The general picture of Popper's philosophy of science, then is this: Hume's philosophy demonstrates that there is a contradiction implicit in traditional empiricism, which holds both that all knowledge is derived from experience *and* that universal propositions (including scientific laws) are verifiable by reference to experience. The contradiction, which Hume himself saw clearly, derives from the attempt to show that, notwithstanding the open-ended nature of experience, scientific laws may be construed as empirical generalisations which are in some way finally confirmable by a 'positive' experience. Popper eliminates the contradiction by rejecting the first of these principles and removing the demand for empirical verification in favour of empirical falsification in the second. Scientific theories, for him, are not inductively inferred from experience, nor is scientific experimentation carried out with a view to verifying or finally establishing the truth of theories; rather, *all knowledge is provisional, conjectural, hypothetical* - we can never finally prove our scientific theories, we can merely (provisionally) confirm or (conclusively) refute them; hence at any given time we have to choose between the potentially infinite number of theories which will explain the set of phenomena under investigation. Faced with this choice, we can only eliminate those theories which are demonstrably false, and rationally choose between the remaining, unfalsified theories. Hence Popper's emphasis on the importance of the critical spirit to science - for him critical thinking is the very essence of rationality. For it is only by critical thought that we can eliminate false theories, and determine which of the remaining theories is the best available one, in the sense of possessing the highest level of explanatory force and predictive power. It is precisely this kind of critical thinking which is conspicuous by its absence in contemporary Marxism and in psychoanalysis.

Probability, Knowledge and Verisimilitude

In the view of many social scientists, the more probable a theory is, the *better* it is, and if we have to choose between two theories which are equally strong in terms of their explanatory power, and differ only in that one is probable and the other is improbable, then we should choose the former. Popper

rejects this. Science, or to be precise, the working scientist, is interested, in Popper's view, in theories with a high informative content, because such theories possess a high predictive power and are consequently highly testable. But if this is true, Popper argues, then, paradoxical as it may sound, the more *improbable* a theory is the better it is scientifically, because the probability and informative content of a theory vary inversely - the higher the informative content of a theory the lower will be its probability, for the more information a statement contains, the greater will be the number of ways in which it may turn out to be false. Thus the statements which are of special interest to the scientist are those with a high informative content and (consequentially) a low probability, which nevertheless come close to the truth. Informative content, which is in inverse proportion to probability, is in direct proportion to testability. Consequently the severity of the test to which a theory can be subjected, and by means of which it is falsified or corroborated, is all-important.

For Popper, all scientific criticism must be piecemeal, i.e. he holds that it is not possible to question every aspect of a theory at once. More precisely, while attempting to resolve a particular problem a scientist of necessity accepts all kinds of things as unproblematic. These things constitute what Popper terms the ‘background knowledge’. However, he stresses that the background knowledge is *not* knowledge in the sense of being conclusively established; it may be challenged at any time, especially if it is suspected that its uncritical acceptance may be responsible for difficulties which are subsequently encountered. Nevertheless, it is clearly not possible to question both the theory and the background knowledge at the same time (e.g. in conducting an experiment the scientist of necessity assumes that the apparatus used is in working order).

How then can one be certain that one is questioning the right thing? The Popperian answer is that we cannot have absolute certainty here, but repeated tests usually show where the trouble lies. Even observation statements, Popper maintains, are fallible, and science in his view is not a quest for certain knowledge, but an evolutionary process in which hypotheses or conjectures are imaginatively proposed and tested in order to explain facts or to solve problems. Popper emphasises both the importance of questioning the background knowledge when the need arises, and the significance of the fact that observation-statements are theory-laden, and hence fallible. For while falsifiability is simple as a logical principle, in practice it is exceedingly complicated - no single observation can ever be taken to falsify a theory, for there is always the possibility (a) that the observation itself is mistaken, or (b) that the assumed background knowledge is faulty or defective.

Popper was initially uneasy with the concept of truth, and in his earliest writings he avoided asserting that a theory which is corroborated is true - for clearly if every theory is an open-ended hypothesis, as he maintains, then *ipso facto* it has to be at least potentially false. For this reason Popper restricted himself to the contention that a theory which is falsified is false and is known to be such, and that a theory which replaces a falsified theory (because it has a higher empirical content than the latter, and explains what has falsified it) is a ‘better theory’ than its predecessor. However, he came to accept Tarski's reformulation of the correspondence theory of truth, and in *Conjectures and Refutations* (1963) he integrated the concepts of truth and content to frame the metalogical concept of ‘truthlikeness’ or ‘*verisimilitude*’. A ‘good’ scientific theory, Popper thus argued, has a higher level of verisimilitude than its rivals, and he explicated this concept by reference to the logical consequences of theories. A theory's content is the totality of its

logical consequences, which can be divided into two classes: there is the '*truth-content*' of a theory, which is the class of true propositions which may be derived from it, on the one hand, and the '*falsity-content*' of a theory, on the other hand, which is the class of the theory's false consequences (this latter class may of course be empty, and in the case of a theory which is true is necessarily empty).

Popper offered two methods of comparing theories in terms of verisimilitude, the qualitative and quantitative definitions. On the qualitative account, Popper asserted:

> Assuming that the truth-content and the falsity-content of two theories t_1 and t_2 are comparable, we can say that t_2 is more closely similar to the truth, or corresponds better to the facts, than t_1, if and only if either:
>
> (a) the truth-content but not the falsity-content of t_2 exceeds that of t_1, or
>
> (b) the falsity-content of t_1, but not its truth-content, exceeds that of t_2. (*Conjectures and Refutations*, 233).

Here, verisimilitude is defined in terms of subclass relationships: t_2 has a higher level of verisimilitude than t_1 if and only if their truth- and falsity-contents are comparable through subclass relationships, and *either* (a) t_2's truth-content includes t_1's and t_2's falsity-content, if it exists, is included in, or is the same as, t_1's, *or* (b) t_2's truth-content includes or is the same as t_1's and t_2's falsity-content, if it exists, is included in t_1's.

On the quantitative account, verisimilitude is defined by assigning quantities to contents, where the index of the content of a given theory is its logical improbability (given again that content and probability vary inversely). Formally, then, Popper defines the quantitative verisimilitude which a statement 'a' possesses by means of a formula:

$$Vs(a)=Ct_T(a) - Ct_F(a),$$

where Vs(a) represents the verisimilitude of 'a', $Ct_T(a)$ is a measure of the truth-content of 'a', and $Ct_F(a)$ is a measure of its falsity-content.

The utilisation of either method of computing verisimilitude shows, Popper held, that even if a theory t_2 with a higher content than a rival theory t_1 is subsequently falsified, it can still legitimately be regarded as a better theory than t_1, and 'better' is here now understood to mean t_2 is *closer to the truth* than t_1. Thus scientific progress involves, on this view, the abandonment of partially true, but falsified, theories, for theories with a higher level of verisimilitude, i.e., which approach more closely to the truth. In this way, verisimilitude allowed Popper to mitigate what many saw as the pessimism of an anti-inductivist

philosophy of science which held that most, if not all scientific theories are false, and that a true theory, even if discovered, could not be *known* to be such. With the introduction of the new concept, Popper was able to represent this as an essentially optimistic position in terms of which we can legitimately be said to have reason to believe that science makes progress towards the truth through the falsification and corroboration of theories. Scientific progress, in other words, could now be represented as progress *towards* the truth, and experimental corroboration could be seen an *indicator* of verisimilitude.

However, in the 1970's a series of papers published by researchers such as Miller, Tichý, and Grünbaum in particular revealed fundamental defects in Popper's formal definitions of verisimilitude. The significance of this work was that verisimilitude is largely important in Popper's system because of its application to theories which are known to be *false*. In this connection, Popper had written:

> Ultimately, the idea of verisimilitude is most important in cases where we know that we have to work with theories which are *at best* approximations—that is to say, theories of which we know that they cannot be true. (This is often the case in the social sciences). In these cases we can still speak of better or worse approximations to the truth (and we therefore do not need to interpret these cases in an instrumentalist sense). (*Conjectures and Refutations*, 235).

For these reasons, the deficiencies discovered by the critics in Popper's formal definitions were seen by many as devastating, precisely because the most significant of these related to the levels of verisimilitude of *false* theories. In 1974, Miller and Tichý, working independently of each other, demonstrated that the conditions specified by Popper in his accounts of both qualitative and quantitative verisimilitude for comparing the truth- and falsity-contents of theories can be satisfied only when the theories are *true*. In the crucially important case of false theories, however, Popper's definitions are formally defective. For while Popper had believed that verisimilitude intersected positively with his account of corroboration, in the sense that he viewed an improbable theory which had withstood critical testing as one the truth-content of which is great relative to rival theories, while its falsity-content (if it exists) would be relatively low, Miller and Tichý proved, on the contrary, that in the case of a false theory $t_2$which has excess content over a rival theory false $t_1$both the truth-content *and* the falsity-content of $t_2$will exceed that of t_1. With respect to theories which are false, therefore, Popper's conditions for comparing levels of verisimilitude, whether in quantitative and qualitative terms, can never be met.

Commentators on Popper, with few exceptions, had initially attached little importance to his theory of verisimilitude. However, after the failure of Popper's definitions in 1974, some critics came to see it as central to his philosophy of science, and consequentially held that the whole edifice of the latter had been subverted. For his part, Popper's response was two-fold. In the first place, while acknowledging the deficiencies in his own formal account ("my main mistake was my failure to see at once that … if the content of a false statement *a* exceeds that of a statement *b*, then the truth-content of *a* exceeds the truth-content of *b*, and the same holds of their falsity-contents", *Objective Knowledge*, 371), Popper argued that "I do think that we should not conclude from the failure of my attempts to solve the problem [of defining verisimilitude] that the problem cannot be solved" (*Objective Knowledge*, 372), a point of view

which was to precipitate more than two decades of important technical research in this field. At another, more fundamental level, he moved the task of formally defining the concept from centre-stage in his philosophy of science, by protesting that he had never intended to imply "that degrees of verisimilitude ... can ever be numerically determined, except in certain limiting cases" (*Objective Knowledge*, 59), and arguing instead that the chief value of the concept is heuristic and intuitive, in which the absence of an adequate formal definition is not an insuperable impediment to its utilisation in the actual appraisal of theories relativised to problems in which we have an interest. The thrust of the latter strategy seems to many to genuinely reflect the significance of the concept of verisimilitude in Popper's system, but it has not satisfied all of his critics.

Social and Political Thought -- The Critique of Historicism and Holism

Given Popper's personal history and background, it is hardly surprising that he developed a deep and abiding interest in social and political philosophy. However, it is worth emphasising that his angle of approach to these fields is through a consideration of the nature of the social sciences which seek to describe and explicate them systematically, particularly history. It is in this context that he offers an account of the nature of scientific prediction, which in turn allows him a point of departure for his attack upon totalitarianism and all its intellectual supports, especially holism and historicism. In this context holism is to be understood as the view that human social groupings are greater than the sum of their members, that such groupings are 'organic' entities in their own right, that they act on their human members and shape their destinies, and that they are subject to their own independent laws of development. Historicism, which is closely associated with holism, is the belief that history develops inexorably and necessarily according to certain principles or rules towards a determinate end (as for example in the dialectic of Hegel, which was adopted and implemented by Marx). The link between holism and historicism is that the holist believes that individuals are essentially formed by the social groupings to which they belong, while the historicist - who is usually also a holist - holds that we can understand such a social grouping only in terms of the internal principles which determine its development.

These beliefs lead to what Popper calls 'The Historicist Doctrine of the Social Sciences', the views (a) that the principal task of the social sciences is to make predictions about the social and political development of man, and (b) that the task of politics, once the key predictions have been made, is, in Marx's words, to lessen the 'birth pangs' of future social and political developments. Popper thinks that this view of the social sciences is both theoretically misconceived (in the sense of being based upon a view of natural science and its methodology which is totally wrong), and socially dangerous, as it leads inevitably to totalitarianism and authoritarianism - to centralised governmental control of the individual and the attempted imposition of large-scale social planning. Against this Popper strongly advances the view that any human social grouping is no more (or less) than the sum of its individual members, that what happens in history is the (largely unplanned and unforeseeable) result of the actions of such

individuals, and that large scale social planning to an antecedently conceived blueprint is inherently misconceived - and inevitably disastrous - precisely because human actions have consequences which cannot be foreseen. Popper, then, is an historical *indeterminist*, insofar as he holds that history does not evolve in accordance with intrinsic laws or principles, that in the absence of such laws and principles unconditional prediction in the social sciences is an impossibility, and that there is no such thing as historical necessity.

The link between Popper's theory of knowledge and his social philosophy is his fallibilism - just as we make theoretical progress in science by deliberately subjecting our theories to critical scrutiny, and abandoning those which have been falsified, so too, Popper holds, the critical spirit can and should be sustained at the social level. More specifically, the open society can be brought about only if it is possible for the individual citizen to evaluate critically the consequences of the implementation of government policies, which can then be abandoned or modified in the light of such critical scrutiny - in such a society, the rights of the individual to criticise administrative policies will be formally safeguarded and upheld, undesirable policies will be eliminated in a manner analogous to the elimination of falsified scientific theories, and differences between people on social policy will be resolved by critical discussion and argument rather than by force. The open society as thus conceived of by Popper may be defined as ‘an association of free individuals respecting each other's rights within the framework of mutual protection supplied by the state, and achieving, through the making of responsible, rational decisions, a growing measure of humane and enlightened life’ (Levinson, R.B. *In Defense of Plato*, 17). As such, Popper holds, it is not a utopian ideal, but an empirically realised form of social organisation which, he argues, is in every respect superior to its (real or potential) totalitarian rivals. But he does not engage in a moral defence of the ideology of liberalism; rather his strategy is the much deeper one of showing that totalitarianism is typically based upon historicist and holist presuppositions, and of demonstrating that these presuppositions are fundamentally incoherent.

Scientific Knowledge, History, and Prediction

At a very general level, Popper argues that historicism and holism have their origins in what he terms ‘one of the oldest dreams of mankind - the dream of prophecy, the idea that we can know what the future has in store for us, and that we can profit from such knowledge by adjusting our policy to it.’ (*Conjectures and Refutations*, 338). This dream was given further impetus, he speculates, by the emergence of a genuine predictive capability regarding such events as solar and lunar eclipses at an early stage in human civilisation, which has of course become increasingly refined with the development of the natural sciences and their concomitant technologies. The kind of reasoning which has made, and continues to make, historicism plausible may, on this account, be reconstructed as follows: if the application of the laws of the natural sciences can lead to the successful prediction of such future events as eclipses, then surely it is reasonable to infer that knowledge of the laws of history as yielded by a social science or sciences (assuming that such laws exist) would lead to the successful prediction of such future social phenomena as revolutions? Why should it be possible to predict an eclipse, but not a revolution? Why can we not conceive of a social science which could and would function as the

theoretical natural sciences function, and yield precise unconditional predictions in the appropriate sphere of application? These are amongst the questions which Popper seeks to answer, and in doing so, to show that they are based upon a series of misconceptions about the nature of science, and about the relationship between scientific laws and scientific prediction.

His first argument may be summarised as follows: in relation to the critically important concept of prediction, Popper makes a distinction between what he terms ‘conditional scientific predictions’, which have the form ‘If X takes place, then Y will take place’, and ‘unconditional scientific prophecies’, which have the form ‘Y will take place’. Contrary to popular belief, it is the former rather than the latter which are typical of the natural sciences, which means that typically prediction in natural science is conditional and limited in scope - it takes the form of hypothetical assertions stating that certain specified changes will come about if particular specified events antecedently take place. This is not to deny that ‘unconditional scientific prophecies’, such as the prediction of eclipses, for example, do take place in science, and that the theoretical natural sciences make them possible. However, Popper argues that (a) these unconditional prophecies are not *characteristic* of the natural sciences, and (b) that the mechanism whereby they occur, in the very limited way in which they do, is not understood by the historicist.

What is the mechanism which makes unconditional scientific prophecies possible? The answer is that such prophecies can sometimes be derived from a combination of conditional predictions (themselves derived from scientific laws) *and* existential statements specifying that the conditions in relation to the system being investigated are fulfilled. Schematically, this can be represented as follows:

[C.P. + E.S.]=U.P.

where C.P.=Conditional Prediction; E.S.=Existential Statement; U.P.=Unconditional Prophecy. The most common examples of unconditional scientific prophecies in science relate to the prediction of such phenomena as lunar and solar eclipses and comets.

Given, then, that this is the mechanism which generates unconditional scientific prophecies, Popper makes two related claims about historicism: (a) That the historicist does not in fact derive his unconditional scientific prophecies in this manner from conditional predictions, and (b) the historicist *cannot* do so because long-term unconditional scientific prophecies can be derived from conditional predictions only if they apply to systems which are well-isolated, stationary, and recurrent (like our solar system). Such systems are quite rare in nature, and human society is most emphatically not one of them.

This, then, Popper argues, is the reason why it is a fundamental mistake for the historicist to take the unconditional scientific prophecies of eclipses as being typical and characteristic of the predictions of natural science - in fact such predictions are possible only because our solar system is a stationary and repetitive system which is isolated from other such systems by immense expanses of empty space. The solar system aside, there are very few such systems around for scientific investigation - most of the others are confined to the field of biology, where unconditional prophecies about the life-cycles of organisms are made possible by the existence of precisely the same factors. Thus one of the fallacies

committed by the historicist is to take the (relatively rare) instances of unconditional prophecies in the natural science as constituting the essence of what scientific prediction is, to fail to see that such prophecies apply only to systems which are isolated, stationary, and repetitive, and to seek to apply the method of scientific prophecy to human society and human history. The latter, of course, is *not* an isolated system (in fact it's not a system at all), it is constantly changing, and it continually undergoes rapid, non-repetitive development. In the most fundamental sense possible, every event in human history is discrete, novel, quite unique, and ontologically distinct from every other historical event. For this reason, it is impossible in principle that unconditional scientific prophecies could be made in relation to human history - the idea that the successful unconditional prediction of eclipses provides us with reasonable grounds for the hope of successful unconditional prediction regarding the evolution of human history turns out to be based upon a gross misconception, and is quite false. As Popper himself concludes, "The fact that we predict eclipses does not, therefore, provide a valid reason for expecting that we can predict revolutions." (*Conjectures and Refutations*, 340).
[Return to Section Headings]

Immutable Laws and Contingent Trends

This argument is one of the strongest that has ever been brought against historicism, cutting, as it does, right to the heart of one of its main theoretical presuppositions. However, it is not Popper's only argument against it. An additional mistake which he detects in historicism is the failure of the historicist to distinguish between scientific *laws* and *trends*, which is also frequently accompanied by a simple logical fallacy. The fallacy is that of inferring from the fact that our understanding of any (past) historical event - such as, for example, the French Revolution - is in direct proportion to our knowledge of the antecedent conditions which led to that event, that knowledge of all the antecedent conditions of some future event is possible, and that such knowledge would make that future event precisely predictable. For the truth is that the number of factors which predate and lead to the occurrence of any event, past, present, or future, is indefinitely large, and therefore knowledge of all of these factors is impossible, even in principle. What gives rise to the fallacy is the manner in which the historian (necessarily) selectively isolates a finite number of the antecedent conditions of some past event as being of particular importance, which are then somewhat misleadingly termed ‘the causes’ of that event, when in fact what this means is that they are the specific conditions which a particular historian or group of historians take to be more *relevant* than any other of the indefinitely large number of such conditions (for this reason, most historical debates range over the question as to whether the conditions thus specified are the *right* ones). While this kind of selectivity may be justifiable in relation to the treatment of any past event, it has no basis whatsoever in relation to the future - if we now select, as Marx did, the ‘relevant’ antecedent conditions for some future event, the likelihood is that we will select wrongly.

The historicist's failure to distinguish between scientific laws and trends is equally destructive of his cause. This failure makes him think it possible to explain change by discovering trends running through past history, and to anticipate and predict future occurrences on the basis of such observations. Here Popper points out that there is a critical difference between a trend and a scientific law, the failure to observe which is fatal. For a scientific law is universal in form, while a trend can be expressed only as a

singular existential statement. This logical difference is crucial because unconditional predictions, as we have already seen, can be based only upon conditional ones, which themselves must be derived from scientific laws. Neither conditional nor unconditional predictions can be based upon trends, because these may change or be reversed with a change in the conditions which gave rise to them in the first instance. As Popper puts it, there can be no doubt that "the habit of confusing trends with laws, together with the intuitive observation of trends such as technical progress, inspired the central doctrines of ... historicism." (*The Poverty of Historicism*, 116). Popper does not, of course, dispute the existence of trends, nor does he deny that the observation of trends can be of practical utility value - but the essential point is that a trend is something which *itself* ultimately stands in need of scientific explanation, and it cannot therefore function as the frame of reference in terms of which anything else can be scientifically explained or predicted.

A point which connects with this has to do with the role which the evolution of human knowledge has played in the historical development of human society. It is incontestable that, as Marx himself observed, there has been a causal link between the two, in the sense that advances in scientific and technological knowledge have given rise to widespread global changes in patterns of human social organisation and social interaction, which in turn have led to social structures (e.g. educational systems) which further growth in human knowledge. In short, the evolution of human history has been strongly influenced by *the growth of human knowledge*, and it is extremely likely that this will continue to be the case - all the empirical evidence suggests that the link between the two is progressively consolidating. However, this gives rise to further problems for the historicist. In the first place, the statement that ‘if there is such a thing as growing human knowledge, then we cannot anticipate today what we shall know only tomorrow’ is, Popper holds, intuitively highly plausible. Moreover, he argues, it is logically demonstrable by a consideration of the implications of the fact that no scientific predictor, human or otherwise, can possibly predict, by scientific methods, its own future results. From this it follows, he holds, that ‘no society can predict, scientifically, its own future states of knowledge’. (*The Poverty of Historicism*, vii). Thus, while the future evolution of human history is extremely likely to be influenced by new developments in human knowledge, as it always has in the past, we cannot now scientifically determine what such knowledge will be. From this it follows that if the future holds any new discoveries or any new developments in the growth of our knowledge (and given the fallible nature of the latter, it is inconceivable that it does not), then it is impossible for us to predict them now, and it is therefore impossible for us to predict the future development of human history now, given that the latter will, at least in part, be determined by the future growth of our knowledge. Thus once again historicism collapses - the dream of a theoretical, predictive science of history is unrealisable, because it is an impossible dream.

Popper's arguments against holism, and in particular his arguments against the propriety of large-scale planning of social structures, are interconnected with his demonstration of the logical shortcomings of the presuppositions of historicism. Such planning (which actually took place, of course, in the USSR, in China, and in Cambodia, for example, under totalitarian regimes which accepted forms of historicism and holism), Popper points out, is necessarily structured in the light of the predictions which have been made about future history on the basis of the so-called ‘laws’ which historicists such as Marx and Mao claimed to have discovered in relation to human history. Accordingly, recognition that there are no such

laws, and that unconditional predictions about future history are based, at best, upon nothing more substantial than the observation of contingent trends, shows that, from a purely theoretical as well as a practical point of view, large-scale social planning is indeed a recipe for disaster. In summary, unconditional large-scale planning for the future is theoretically as well as practically misguided, because, again, part of what we are planning for is our future knowledge, and our future knowledge is not something which we can in principle now possess - we cannot adequately plan for unexpected advances in our future knowledge, or for the effects which such advances will have upon society as a whole. The acceptance of historical indeterminism, then, as the only philosophy of history which is commensurate with a proper understanding of the nature of scientific knowledge, fatally undermines both historicism and holism.

Popper's critique of both historicism and holism is balanced, on the positive side, by his strong defence of the open society, the view, again, that a society is equivalent to the sum of its members, that the actions of the members of society serve to fashion and to shape it, not conversely, and that the social consequences of intentional actions are very often, and very largely, unintentional. This is why Popper himself advocates what he (rather unfortunately) terms ‘piecemeal social engineering’ as the central mechanism for social planning - for in utilising this mechanism intentional actions are directed to the achievement of one specific goal at a time, which makes it possible to monitor the situation to determine whether adverse unintended effects of intentional actions occur, in order to correct and readjust when this proves necessary. This, of course, parallels precisely the critical testing of theories in scientific investigation. This approach to social planning (which is explicitly based upon the premise that we do not, because we cannot, know what the future will be like) encourages attempts to put right what is problematic in society - generally-acknowledged social ills - rather than attempts to impose some preconceived idea of the ‘good’ upon society as a whole. For this reason, in a genuinely open society piecemeal social engineering goes hand-in-hand for Popper with *negative* utilitarianism (the attempt to minimise the amount of misery, rather than, as with positive utilitarianism, the attempt to maximise the amount of happiness). The state, he holds, should concern itself with the task of progressively formulating and implementing policies designed to deal with the social problems which actually confront it, with the goal of eliminating human misery and suffering to the highest possible degree. The positive task of increasing social and personal happiness, by contrast, can and should be should be left to individual citizens (who may, of course, act collectively to this end), who, unlike the state, have at least a chance of achieving this goal, but who in a free society are rarely in a position to systematically subvert the rights of others in the pursuit of idealised objectives. Thus in the final analysis for Popper the activity of problem-solving is as definitive of our humanity at the level of social and political organisation as it is at the level of science, and it is this key insight which unifies and integrates the broad spectrum of his thought.
[Return to Section Headings]

Critical Evaluation

While it cannot be said that Popper was a modest man, he took criticism of his theories very seriously, and spent much of his time in his later years endeavouring to show that such criticisms were either based

upon misunderstandings, or that his theories could, without loss of integrity, be made compatible with new and important insights (such as Kuhn's distinction between normal and revolutionary science). The following is a summary of some of the main criticisms which he has had to address.

1. Popper professes to be anti-conventionalist, and his commitment to the correspondence theory of truth places him firmly within the realist's camp. Yet, following Kant, he strongly repudiates the positivist/empiricist view that basic statements (i.e. present-tense observation statements about sense-data) are infallible, and argues convincingly that such basic statements are not mere ‘reports’ of passively registered sensations. Rather they are descriptions of what is observed as interpreted by the observer with reference to a determinate theoretical framework. This is why Popper repeatedly emphasises that basic statements are not infallible, and it indicates what he means when he says that they are ‘theory laden’ - perception itself is an active process, in which the mind assimilates data by reference to an assumed theoretical backdrop. He accordingly asserts that basic statements themselves are open-ended hypotheses: they have a certain causal relationship with experience, but they are not *determined* by experience, and they cannot be verified or confirmed by experience. However, this poses a difficulty regarding the consistency of Popper's theory: if a theory X is to be genuinely testable (and so scientific) it must be possible to determine whether or not the basic propositions which would, if true, falsify it, are *actually* true or false (i.e. whether its potential falsifiers are actual falsifiers). But how can this be known, if such basic statements cannot be verified by experience? Popper's answer is that ‘basic statements are not justifiable by our immediate experiences, but are .... accepted by an act, a free decision’. (*Logic of Scientific Discovery*, 109). However, and notwithstanding Popper's claims to the contrary, this itself seems to be a refined form of conventionalism - it implies that it is almost entirely an arbitrary matter whether it is accepted that a potential falsifier is an actual one, and consequently that the falsification of a theory is itself the function of a ‘free’ and arbitrary act. It also seems very difficult to reconcile this with Popper's view that science progressively moves closer to the truth, conceived of in terms of the correspondence theory, for this kind of conventionalism is inimical to this (classical) conception of truth.

2. As Lakatos has pointed out, Popper's theory of demarcation hinges quite fundamentally on the assumption that there are such things as critical tests, which either conclusively falsify a theory, or give it a strong measure of corroboration. Popper himself is fond of citing, as an example of such a critical test, the resolution, by Adams and Leverrier, of the problem which the anomalous orbit of Uranus posed for nineteenth century astronomers. Both men independently came to the conclusion that, assuming Newtonian mechanics to be precisely correct, the observed divergence in the elliptical orbit of Uranus could be explained if the existence of a seventh, as yet unobserved outer planet was posited. Further, they were able, again within the framework of Newtonian mechanics, to calculate the precise position of the ‘new’ planet. Thus when subsequent research by Galle at the Berlin observatory revealed that such a planet (Neptune) did in fact exist, and was situated precisely where Adams and Leverrier had calculated, this was hailed as by all and sundry as a magnificent triumph for Newtonian physics: in Popperian terms, Newton's theory had been subjected to a critical test, and had passed with flying colours. Popper himself refers to this strong corroboration of Newtonian physics as ‘the most startling and convincing success of any human intellectual achievement’. Yet Lakatos flatly denies that there are critical tests, in the Popperian sense, in science, and argues the point convincingly by turning the above example of an alleged critical test on its head. What, he asks, would have happened if Galle had *not* found the planet

Neptune? Would Newtonian physics have been abandoned, or would Newton's theory have been falsified? The answer is clearly not, for Galle's failure could have been attributed to any number of causes other than the falsity of Newtonian physics (e.g. the interference of the earth's atmosphere with the telescope, the existence of an asteroid belt which hides the new planet from the earth, etc). The point here is that the ‘falsification/corroboration’ disjunction offered by Popper is far too logically neat: non-corroboration is *not necessarily* falsification, and falsification of a high-level scientific theory is never brought about by an isolated observation or set of observations. Such theories are, it is now generally accepted, highly resistant to falsification. They are falsified, if at all, Lakatos argues, not by Popperian critical tests, but rather within the elaborate context of the research programmes associated with them gradually grinding to a halt, with the result that an ever-widening gap opens up between the facts to be explained, and the research programmes themselves. (Lakatos, I. *The Methodology of Scientific Research Programmes*, passim). Popper's distinction between the logic of falsifiability and its applied methodology does not in the end do full justice to the fact that all high-level theories grow and live despite the existence of anomalies (i.e. events/phenomena which are incompatible with the theories). The existence of such anomalies is not usually taken by the working scientist as an indication that the theory in question is false; on the contrary, he will usually, and necessarily, assume that the auxiliary hypotheses which are associated with the theory can be modified to incorporate, and explain, existing anomalies.

3. Scientific laws are expressed by universal statements (i.e. they take the logical form ‘All A's are X’, or some equivalent) which are therefore concealed conditionals - they have to be understood as hypothetical statements asserting what would be the case under certain ideal conditions. In themselves they are not *existential* in nature. Thus ‘All A's are X’ means ‘If anything is an A, then it is X’. Since scientific laws are non-existential in nature, they logically cannot imply any basic statements, since the latter are explicitly existential. The question arises, then, as to how any basic statement can falsify a scientific law, given that basic statements are not deducible from scientific laws in themselves? Popper answers that scientific laws are always taken in *conjunction with* statements outlining the ‘initial conditions’ of the system under investigation; these latter, which are singular existential statements, do, when combined with the scientific law, yield hard and fast implications. Thus, the law ‘All A's are X’, together with the initial condition statement ‘There is an A at Y’, yields the implication ‘The A at Y is X’, which, if false, falsifies the original law.

This reply is adequate only if it is true, as Popper assumes, that *singular* existential statements will always do the work of bridging the gap between a universal theory and a prediction. Hilary Putnam in particular has argued that this assumption is false, in that in some cases at least the statements required to bridge this gap (which he calls ‘auxiliary hypotheses’) are general rather than particular, and consequently that when the prediction turns out to be false we have no way of knowing whether this is due to the falsity of the scientific law *or* the falsity of the auxiliary hypotheses. The working scientist, Putnam argues, always initially assumes that it is the latter, which shows not only that scientific laws are, *contra* Popper, highly resistant to falsification, but also why they are so highly resistant to falsification.

Popper's final position is that he acknowledges that it is impossible to discriminate science from non-science on the basis of the falsifiability of the scientific statements *alone*; he recognizes that scientific theories are predictive, and consequently prohibitive, *only* when taken in conjunction with auxiliary

hypotheses, and he also recognizes that readjustment or modification of the latter is an integral part of scientific practice. Hence his final concern is to outline conditions which indicate when such modification is genuinely scientific, and when it is merely *ad hoc*. This is itself clearly a major alteration in his position, and arguably represents a substantial retraction on his part: Marxism can no longer be dismissed as ‘unscientific’ simply because its advocates preserved the theory from falsification by modifying it (for in general terms, such a procedure, it now transpires, is perfectly respectable scientific practice). It is now condemned as unscientific by Popper because the only *rationale* for the modifications which were made to the original theory was to ensure that it evaded falsification, and so such modifications were *ad hoc*, rather than scientific. This contention - though not at all implausible - has, to hostile eyes, a somewhat contrived air about it, and is unlikely to worry the convinced Marxist. On the other hand, the shift in Popper's own basic position is taken by some critics as an indicator that falsificationism, for all its apparent merits, fares no better in the final analysis than verificationism.

Truthlikeness

While *truth* is the aim of inquiry, some falsehoods seem to realize this aim better than others. Some truths better realize the aim than other truths. And perhaps even some falsehoods realize the aim better than some truths do. The dichotomy of the class of propositions into truths and falsehoods should thus be supplemented with a more fine-grained ordering -- one which classifies propositions according to their *closeness* to the truth, their degree of truthlikeness or verisimilitude. The problem of truthlikeness is to give an adequate account of the concept and to explore its logical properties and its applications to epistemology and methodology.

In §1 we will examine the basic assumptions which generate the problem of truthlikeness, which in part explain why the problem emerged when it did. Attempted solutions to the problem quickly proliferated, but they can all be gathered together into two broad lines of attack. The first, the content approach (§2), was initiated by Popper in his ground-breaking work. However, because it treats truthlikeness as a function of just two variables, neither Popper's original proposals, nor subsequent attempts to elaborate them, can fully capture the richness of the concept. The second, the similarity approach (§3), takes the *likeness* in *truthlikeness* seriously Although it promises to catch more of the complexity of the concept than does the content approach, it faces two serious problems: whether the approach can be suitably generalized to complex examples (§5), and whether it can be developed in a way that is translation invariant (§6).

---

1. The Problem

Truth, perhaps even more than beauty and goodness, has been the target of an extraordinary amount of philosophical dissection and speculation. This is unsurprising. After all, truth is the primary aim of all inquiry and a necessary condition of knowledge. And yet, as redundancy theorists have emphasized, there is something disarmingly simple about truth. That *the number of planets is ten* is true just in case, well, … the number of planets is ten. By comparison with truth, the more complex, and perhaps more interesting, concept of truthlikeness has only recently become the subject of serious investigation. The proposition *the number of planets is ten* may be false, but closer to the truth than the proposition that *the number of planets is ten thousand*. Investigation into truthlikeness began with a tiny trickle of activity in the early nineteen sixties; became something of a torrent from the mid seventies until the late eighties; and is now a steady, albeit diminished, current.

Truthlikeness is a relative latecomer to the philosophical scene largely because it wasn't until the latter half of the twentieth century that mainstream philosophers gave up on the Cartesian goal of infallible knowledge. The idea that we are quite possibily, even probably, mistaken in our most cherished beliefs, that they might well be just *false*, was mostly considered tantamount to capitulation to the skeptic. By the middle of the twentieth century, however, it was clear that natural science postulated a very odd world behind the phenomena, one rather remote from our everyday experience, one which renders many of our commonsense beliefs, as well as previous scientific theories, strictly speaking, false. Further, the increasingly rapid turnover of scientific theories suggested that, far from being established as certain, they are ever vulnerable to refutation, and typically are eventually refuted, to be replaced by some new theory. Taking the dismal view, the history of inquiry is a history of theories shown to be false, replaced by other theories awaiting their turn at the guillotine.

Realism affirms that the primary aim of inquiry is the truth of some matter. Epistemic *optimism* affirms that the history of inquiry is one of progress with respect to its primary aim. But *fallibilism* affirms that, typically, our theories are false or very likely to be false, and when shown to be false they are replaced by other false theories. To combine all three ideas, we must affirm that some false propositions better realize the goal of truth -- are closer to the truth -- than others. So the optimistic realist who has discarded infallibilism has a problem -- the problem of truthlikeness.

While a multitude of apparently different solutions to the problem have been proposed, it is now standard to classify them into two main approaches -- the content approach and the likeness approach.

2. The First Assay: the Content Approach

Sir Karl Popper was the first philosopher to take the problem of truthlikeness seriously enough to make an assay on it. This is not surprising, since Popper was also the first prominent realist to embrace a radical fallibilism about science while trumpeting the epistemic superiority of the enterprise.

According to Popper, Hume had shown not only that we can't verify an interesting theory, we can't even render it more probable. Luckily, there is an asymmetry between verification and falsification. While no

finite amount of data can verify or probabilify an interesting scientific theory, they can falsify the theory.. According to Popper, it is the falsifiability of a theory which makes it scientific. In his early work, he implied that the only kind of progress an inquiry can make consists in falsification of theories. This is a little depressing, to say the least. What it lacks is the idea that a succession of falsehoods can constitute genuine cognitive progress. Perhaps this is why, for many years after first publishing these ideas in his 1934 *Logik der Forschung* Popper received a pretty short shrift from the philosophers. If all we can say with confidence is “Missed again!” and “A miss is as good as a mile!”, and the history of inquiry is a sequence of such misses, then epistemic pessimism follows. Popper eventually realized that this naive falsificationism is compatible with optimism provided we have an acceptable notion of verisimilitude (or truthlikeness). If some false hypotheses are closer to the truth than others, if verisimilitude admits of degrees, then the history of inquiry may turn out to be one of steady progress towards the goal of truth. Moreover, it may be reasonable, on the basis of the evidence, to conjecture that our theories are indeed making such progress even though it would be unreasonable to conjecture that they are true simpliciter.

Popper saw very clearly that the concept of truthlikeness is easily confused with the concept of epistemic probability, and that it has often been so confused. (See Popper, 1963 for a history off the confusion). Popper's insight here was undoubtedly facilitated by his deep, and largely unjustified, antipathy to epistemic probability. His starkly falsificationist account favors bold, contentful theories. Degree of informative content varies inversely with probability -- the greater the content the less likely a theory is to be true. So if you are after theories which seem, on the evidence, to be true, then you will eschew those which make bold -- that is, highly unlikely -- predictions. On this picture the quest for theories with high probability must be quite wrongheaded. Certainly we want inquiry to yield true propositions, but not any old truths will do. A tautology is a truth, and as certain as anything can be, but it is never the answer to any interesting inquiry outside mathematics and logic. What we want are deep truths, truths which capture more rather than less, of the whole truth.

What, then, is the source of the widespread confusion between probability and truthlikeness? Epistemic probability measures the degree of seeming to be true, while truthlikeness measures degree of being like the truth. Seeming and being like might at first strike one as closely related, but of course they are rather different. Seeming concerns the appearances whereas being like concerns the objective facts, facts about similarity or likeness. Even more important, there is a difference between being true and being the truth. The truth, of course, has the property of being true, but not every proposition that is true is the truth in the sense required by the aim of inquiry. The truth of a matter at which an inquiry aims has to be the complete, true answer. Thus there are two dimensions along which probability (seeming to be true) and truthlikeness (being like the truth) differ radically.

To see this distinction clearly, and to articulate it, was one of Popper's most significant contributions, not only to the debate about truthlikeness, but to philosophy of science and logic in general. As we will see, however, his deep antagonism to probability combined with his great love affair with boldness was both a blessing and a curse. The blessing: it led him to produce not only the first interesting and important account of truthlikeness, but to initiate a whole approach to the problem -- the content approach (Oddie 1978, 1981 and 1986, Zwart 2000). The curse, as is now almost universally recognized: content alone is insufficient to characterize truthlikeness.

Popper made the first assay on the problem in his famous collection *Conjectures and Refutations*. First, let a matter for investigation be circumscribed by a language L adequate for discussing it. (Popper was a great admirer of Tarski's assay on the concept of truth and strove to model his theory of truthlikeness on Tarski's theory.) The world induces a partition of sentences of L into those that are true and those that are false. The set of all true sentences is thus a complete true account of the world, as far as that investigation goes. It is aptly called the Truth, *T*. *T* is the target of the investigation couched in L. It is the theory that we are seeking, and, if truthlikeness is to make sense, theories other than *T*, even false theories, come more or less close to capturing *T*.

T, the Truth, is a theory only in the technical Tarskian sense, not in the ordinary everyday sense of that term. It is a set of sentences closed under the consequence relation: a consequence of some sentences in the set is also a sentence in the set. T may not be finitely axiomatisable, or even axiomatisable at all. Where the language involves elementary arithmetic it follows (from Gödel's theorem) that *T* won't be axiomatisable. However, it is a perfectly good set of sentences all the same. In general we will follow the Tarski-Popper usage here and call any set of sentences closed under consequence a theory, and we will assume that each proposition we deal with is identified with the theory it generates in this sense. (Note that when theories are classes of sentences, theory *A* logically entails theory *B* just in case *B* is a subset of *A*.)

The complement of *T*, the set of false sentences *F*, is not a theory even in this technical sense. Since falsehoods always entail truths, *F* is not closed under the consequence relation. (This is part of the reason we have no complementary expression like *the Falsth*. The set of false sentences does not describe a possible alternative to the actual world.) But *F* too is a perfectly good set of sentences. The consequences of any theory *A* that can be formulated in L will thus divide its consequences between *T* and *F*. Popper called the intersection of *A* and *T*, the *truth content* of *A* (A_T), and the intersection of A and F, the falsity content of *A* (A_F). Any theory *A* is thus the union of its non-overlapping truth content and falsity content. Note that since every theory entails all logical truths, these will constitute a special set, at the center of *T*, which will be included in every theory, whether true or false.

A false theory will cover some of *F*, but because every false theory has true consequences, it will also overlap with some of *T* (Diagram 1).

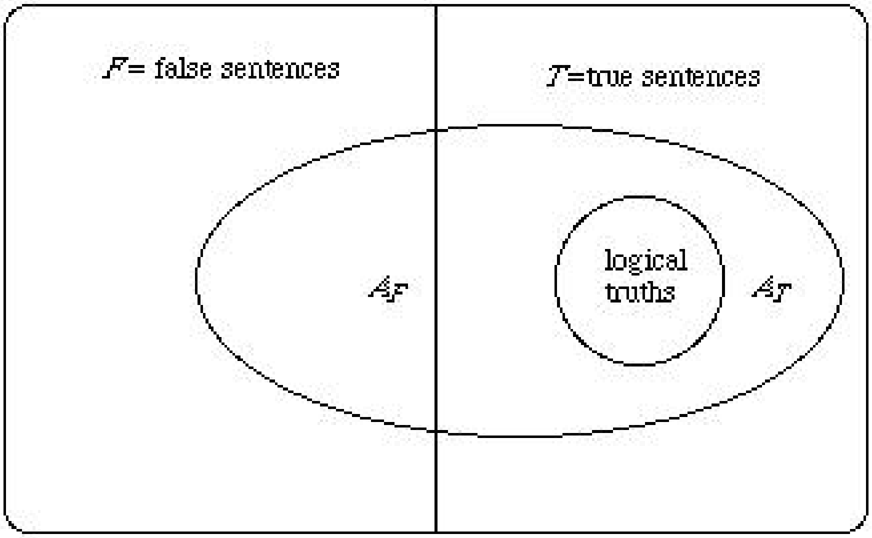

Diagram 1: Truth and falsity contents of false theory *A*

A true theory, however, will only cover *T* (Diagram 2):

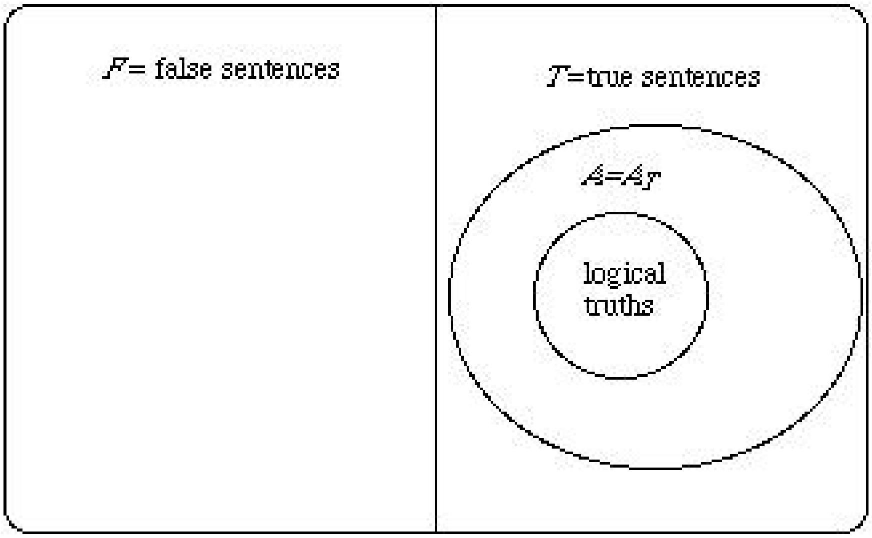

Diagram 2: True theory *A* is identical to its own truth content

Amongst true theories, then, it seems that the more true sentences entailed the closer we get to *T*, hence the more truthlike. Set theoretically that simply means that, where *A* and *B* are both true, *A* will be more truthlike than *B* just in case *B* is a subset of *A* (which for true theories means that the truth content of *B* is a subset of the truth content of *A*.

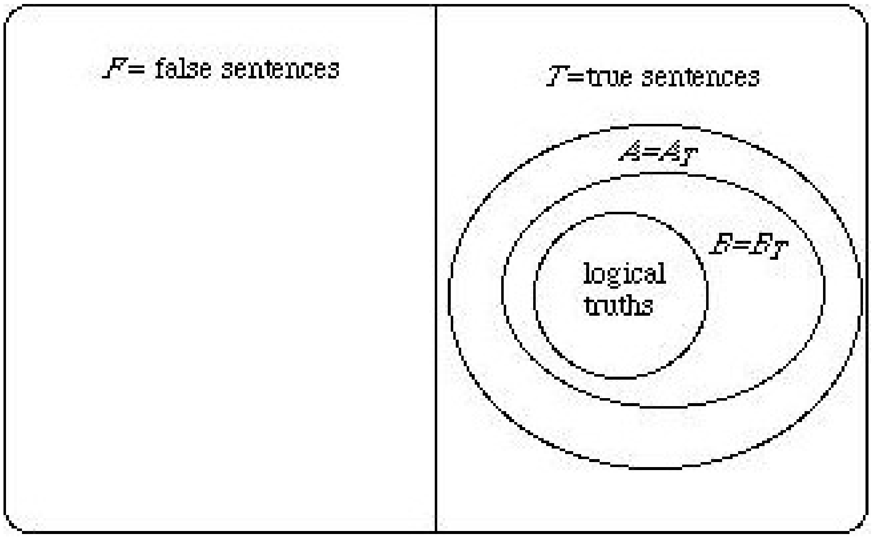

Diagram 3: True theory *A* has more truth content than true theory *B*

This account has some nice features. It induces a partial ordering of truths, with the whole Truth *T* at the top of the ordering: *T* is closer to the Truth than any other true theory. The set of logical truths is at the bottom: further from the Truth than any other true theory. In between these two extremes, true theories are ordered simply by logical strength: the more logical content, the closer to the Truth. Since epistemic probability varies inversely with logical strength, amongst truths the theory with the greatest truthlikeness (*T*) must have the smallest probability, and the theory with the largest probability (the logical truth) is the furthest from the Truth. Popper's love affair with logical strength is thus consummated in his first sketch of an account of truthlikeness.

Popper made a bold and simple generalization of this. Just as truth content (coverage of *T*) counts in favour of truthlikeness, falsity content (coverage of *F*) counts against. In general then, a theory A is closer to the truth if it has more truth content without engendering more falsity content, or has less falsity content without sacrificing truth content (diagram 4):

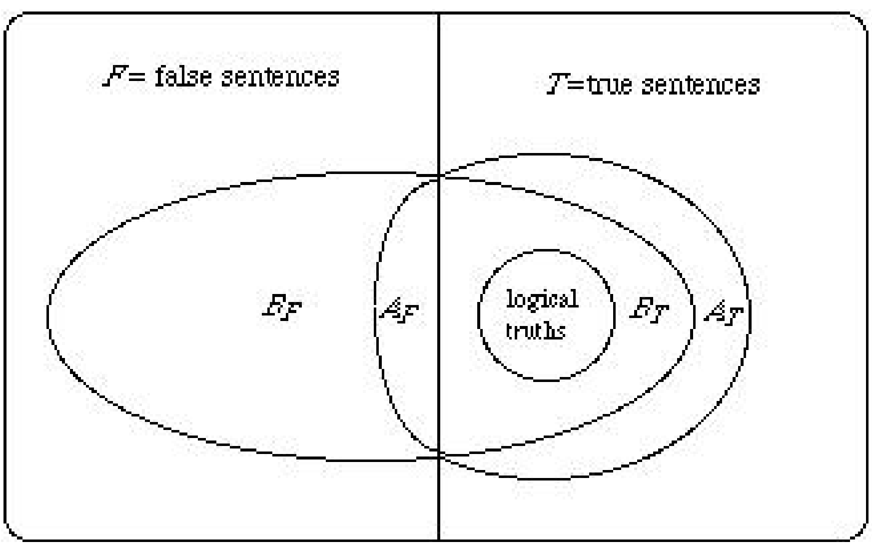

Diagram 4: False theory *A* closer to the Truth than false theory B

This account also has some nice features. It preserves the comparisons of true theories mentioned above. The truth content A_T of a false theory *A* (itself a theory) will clearly be closer to the truth than *A* (diagram

1). More generally, a true theory *A* will be closer to the truth than a false theory *B* provided A's truth content exceeds B's.

Despite these nice features the account suffers the following fatal flaw: it entails that no false theory is closer to the truth than any other. This was shown independently by Pavel Tichý and David Miller (in 1973, reported in Miller 1974, and Tichý 1974). It is instructive to see why. Let us suppose that *A* and *B* are both false, and that *A*'s truth content exceeds *B*'s. Let *a* be a true sentence entailed by *A* but not by *B*. Let *f* be any falsehood entailed by A. Since *A* entails both *a* and *f* the conjunction, *a*&*f* is a falsehood entailed by *A*, and so part of *A*'s falsity content. If *a*&*f* were also part of *B*'s falsity content *B* would entail both *a* and *f*. But then it would entail *a* contrary to the assumption. Hence *a*&*f* is in *A*'s falsity content and not in *B*'s. So *A*'s truth content cannot exceeds *B*'s without *A*'s falsity content also exceeding *B*'s. Suppose now that *B*'s falsity content exceeds *A*'s. Let *g* be some falsehood entailed by *B* but not by *A*, and let *f*, as before, be some falsehood entailed by *A*. The sentence $f \supset g$ is a truth, and since it is entailed by *g*, is in *B*'s truth content. If it were also in *A*'s then both *f* and $f \supset g$ would be consequences of *A* and hence so would *g*, contrary to the assumption. Thus *A*'s truth content lacks a sentence, $f \supset g$, which is in *B*'s. So *B*'s falsity content cannot exceeds *A*'s without *B*'s truth also content exceeding *A*'s. The relationship depicted in diagram 4 simply cannot obtain.

It is tempting to retreat to something like the comparison of truth contents alone. But then we get a result which is almost as bad: that a false theory is the closer to the truth the stonger it is. So, for example, since the false proposition that *all heavenly bodies are made of green cheese* is logically stronger than the false proposition that *all heavenly bodies orbiting the earth are made of green cheese* the former is closer to the truth. And once we know a theory is false we can be confident that tacking any old arbitrary proposition will lead us inexorably closer to the truth. Amongst false theories, brute strength becomes the only criterion of a theory's likeness to truth.

After the failure of Popper's proposal there have been two main variations on the content approach. One stays within Popper's essentially syntactic paradigm, comparing classes of true and false sentences (e.g. Schurz and Weingarter 1987, Newton Smith 1981). The other makes the switch to a more semantic paradigm, searching for a plausible theory of distance between propositions, construing these not as classes of sentences, but rather as classes of possibilities. One main variant takes the class of models of a language as a surrogate for possible states of affairs (Miller 1978a). The other utilizes a semantics of incomplete possible states like those favored by structuralist accounts of scientific theories (Kuipers 1987). The idea which these share in common is that the distance between two propositions is measured by the symmetric difference of the two classes of associated states. Roughly speaking, the larger the symmetric difference, the greater the distance between the two propositions.

If the truth is taken to be represented by a unique model, or complete possible world, then we end up with results very close to Popper's truth content account (Oddie 1978). In particular, false propositions are closer to the truth the stronger they are. However, if we take the structuralist approach then we will take the relevant states of affairs to be “small” states of affairs -- chunks of the world rather than the entire world -- and then the possibility of more fine-grained distinctions between theories opens up. The most promising recent developments exploring this idea are to be found in Volpe 1995.

The fundamental problem with the oriignal pure content approach lies not with the particular proposals but with the underlying strength assumption: that verisimilitude is a function of just two variables -- logical strength and truth value. This assumption has a number of somewhat counterintuitive consequences.

Firstly, it is clear that whatever function of strength and truth value one selects, a given theory A can have only two degrees of verisimilitude: one in case it is false and the other in case it is true. This is obviously wrong. A theory can be false in very many different ways. The proposition that *there are eight planets* is false whether there are nine planets or a thousand planets, but the degree of truthlikeness is much higher in the first case than in the latter. We will see later that the degree of verisimilitude of a true theory may also vary according to where the truth lies.

Secondly, the brute strength assumption entails that if we fix truth value, verisimilitude will vary only on strength. So, for example, two equally strong false theories will have to have the same degree of verisimilitude. That's pretty far-fetched. That there are eight planets and that there are a thousand planets are (intuitively) equally strong, and both are false in fact (assuming that Pluto is indeed a planet), but the latter is much further from the truth.

Finally, how does strength determine verisimilitude amongst false theories? There are really only two plausible candidates: that verisimilitude increases with increasing strength, or that it decreases with increasing strength. Both proposals are at odds with attractive judgements and principles. One does not necessarily make a step toward the truth by reducing the content of a false proposition. The proposition that *the moon is the only heavenly body made of green cheese* is logically stronger than the proposition that *the moon is made of green cheese*, but the latter hardly seems a step towards the truth. Nor does one necessarily make a step toward the truth by increasing the content of a false theory. The false proposition that *all heavenly bodies are made of green cheese* is logically stronger than the false proposition *all heavenly bodies orbiting the earth are made of green cheese* but doesn't seem to constitute progess towards the truth.

3. The Second Assay: the Likeness Approach

In the wake of the collapse of Popper's account two philosophers, working quite independently, suggested a radically different approach: one which takes the likeness in truthlikeness seriously (Tichý 1974, Hilpinen 1976). The shift from content to likeness is also marked by a shift from Popper's syntactic approach to one that is more semantic, one trafficking in possible worlds.

A possible world is a complete possible way for things to be. It is a complete distribution of properties, relations and magnitudes over the appropriate kinds of items. Naturally, these distributions are relativized to a certain collection of features. A proposition carves the class of possibilities into two -- those in which the proposition is true and those in which it is false. Call the class of worlds in which the proposition is true its range. Some have proposed that propositions simply be identified with their ranges, but whether

or not that identification is plausible, certainly the range of a proposition is an important aspect of it. It is the proposition's truth condition. Normal logical relations and operations correspond to well-understood set-theoretic relations and operations on ranges. The range of the conjunction of two proposition is the intersection of the ranges of the two conjuncts. Entailment corresponds to the subset relation on ranges. The actual world is a single point in logical space -- a complete specification of every matter of fact -- and a proposition is true if its range contains the actual world, false otherwise. The Truth is the complete true proposition: that proposition which entails all true propositions. It is none other than the singleton of the actual world. That singleton is the target, the bullseye, the thing at which the most comprehensive inquiry is aiming.

In addition to the set-theoretic structures which underlie the familiar logical relations, the logical space might be structured by similarity or likeness. For example, worlds might be more or less like other worlds. There might be a betweeness relation amongst worlds, or even a fully-fledged distance metric. If that's the case we can start to see how one proposition might be closer to the Truth, the target world, than another. Suppose, for example, that worlds are arranged in similarity spheres nested around the actual world, familiar from the Stalnaker-Lewis approach to counterfactuals. Consider Diagram 5:

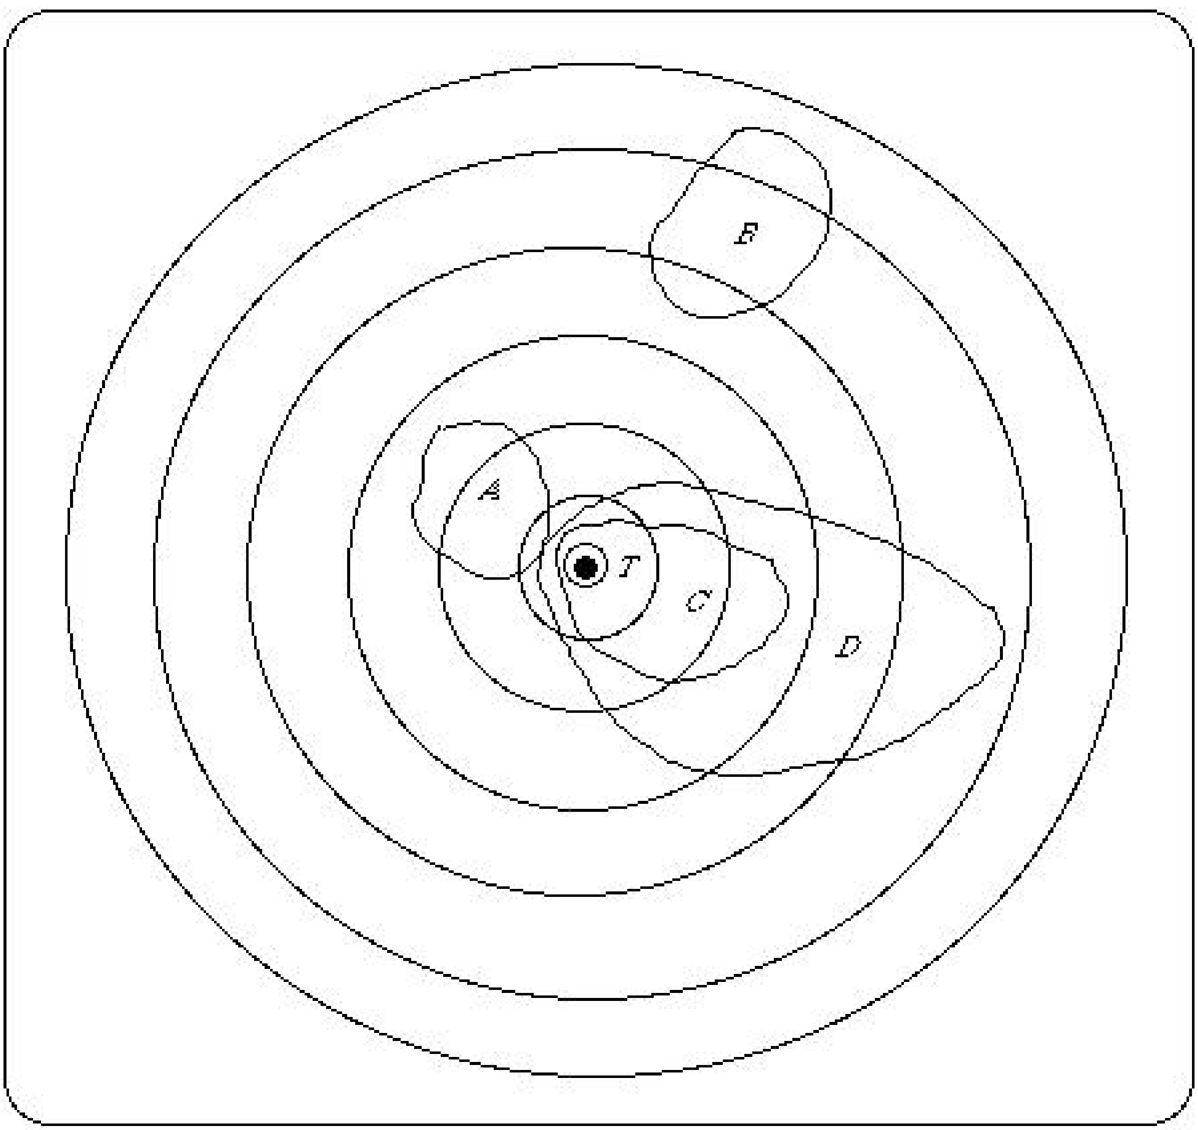

Diagram 5: Verisimilitude by similarity circles

The bullseye is the actual world and the small sphere which includes it is *T*, the Truth. The nested spheres represent likeness to the actual world. A world is less like the actual world the larger the first sphere of which it is a member. Propositions *A* and *B* are false, *C* and *D* are true. A carves out a class of worlds which are rather close to the actual world -- all within spheres two to four -- whereas *B* carves out a class rather far from the actual world -- all within spheres five to seven. Intuitively *A* is closer to the bullseye than is *B*.

The largest sphere which does not overlap at all with a proposition is plausibly a measure of how close the proposition is to being true. Call that the *truth factor*. A proposition *X* is closer to being true than *Y* if the truth factor of *X* is included in the truth factor of *Y*. The truth factor of *A*, for example, is the smallest non-empty sphere, *T* itself, whereas the truth factor of *B* is the fourth sphere, of which *T* is a proper subset.

If a proposition includes the bullseye then of course it is true simpliciter, it has the maximal truth factor (the empty set). So all true propositions are equally close to being true. But truthlikeness is not just a matter of being close to being true. The tautology, *D*, *C* and the Truth itself are equally true, but in that order they increase in their closeness to the whole truth. Taking a leaf out of Popper's book, we can regard closeness to the whole truth as in part a matter of degree of informativeness of a proposition. In the case of the true propositions, this correlates roughly with the smallest sphere which totally includes the proposition. The further out the outermost sphere, the less informative the proposition is, because the larger the area of the logical space which it covers. So, in a way which echoes Popper's account, we could take truthlikeness to be a combination of the truth factor and the content factor.

> *X* is closer to the truth than *Y* if and only if *X* does as well as *Y* on both truth factor and content factor, and better on at least one of those.

Applying this definition we capture two judgements, in addition to those already mentioned, that seem intuitively acceptable: that *C* is closer to the truth than *A*, and that *D* is closer than *B*. (Note, however, that we have here a partial ordering: *A* and *D*, for example, are not ranked). We can derive various apparently desirable features of the relation closer to the truth: for example, that the relation is transitive, asymmetric and irreflexive; that the Truth is closer to the Truth than any other theory; that the tautology is at least as far from the Truth as any other truth; that one cannot make a true theory worse by strengthening it by a truth; that a falsehood is not necessarily improved by adding another falsehood. But there are also some worrying features here. No falsehood can be closer to the truth than any truth, for example. So Newton's theory is no closer to the Truth than the tautology. That's bad.

Stating Hilpinen's account in the above fashion masks its departure from Popper's account.. The incorporation of similarity spheres marks a fundamental break with the pure content approach, and opens up a range of possible new accounts.

One objection to Hilpinen's proposal is that it simply takes as given the similarity relation. Tichý

anticipated this objection, and at the end of his 1974 paper he not only suggested the use of similarity rankings on worlds, but also provided a ranking in simple cases and indicated how to generalize this to more complex cases.

Examples and counterexamples in Tichý 1974 are very simple, framed in a language with three primitives -- *h* (for the state hot), *r* (for rainy) and *w* (for windy). The sentences of this language are taken to express propositions over a dinky little eight-membered logical space. Tichý took judgements of truthlikeness like the following to be self-evident: Suppose that in fact it is hot, raining and windy. Then the proposition that it is cold, and dry and still (expressed by the sentence ~*h*&~*r*&~*w*) is further from the truth than the proposition that it is cold, rainy and windy (expressed by the sentence ~*h*&*r*&*w*). And the proposition that it is cold, dry and windy (expressed by the sentence ~*h*&~*r*&*w*) is somewhere between the two. These kinds of judgements are taken to be core intuitions which any adequate account of truthlikeness would have to deliver, and which Popper's theory patently can not handle. Unlike Popper, Tichý is not trying to find the missing theoretical bridge to epistemic optimism in a fallibilist philosophy of science. Rather, he takes the intuitive concept of truthlikeness to be as much a standard component of the intellectual armory of the folk as is the concept of truth. Doubtless, like the concept of truth, it needs tidying up and trimming down, but he assumes that it is basically sound, and that the job of the philosopher-logician is to explicate it: to give a precise, logically perspicuous, consistent account which captures the core intuitions and excludes core counterintuitions. In the grey areas, where our intuitions are not clear, it is a case of “spoils to the victor” -- the best account of the core intuitions can legislate where the intuitions are fuzzy or contradictory.

4. Similarity in a Simple Logical Space

Consider the eight-membered logical space generated by distributions of truth values through the three basic conditions: hot; rainy; windy. There are eight of them, expressed by the eight propositional constituents, or maximal conjunctions, of which the following are a sample:

w1 *h*&*r*&*w*

w2 *h*&*r*&~*w*

w5 ~*h*&*r*&*w*

w8 ~*h*&~*r*&~*w*

Worlds differ in the distributions of these traits, and a natural, albeit simple, suggestion is to measure the likeness between two worlds by the number of agreements on traits. (This is tantamount to taking distance to be measured by the size of the symmetric difference of generating states. As is well known, this will generate a genuine metric, in particular satisfying the triangular inequality.) If w1 is the actual world this immediately induces a system of nested spheres, but one in which the spheres come with numbers attached:

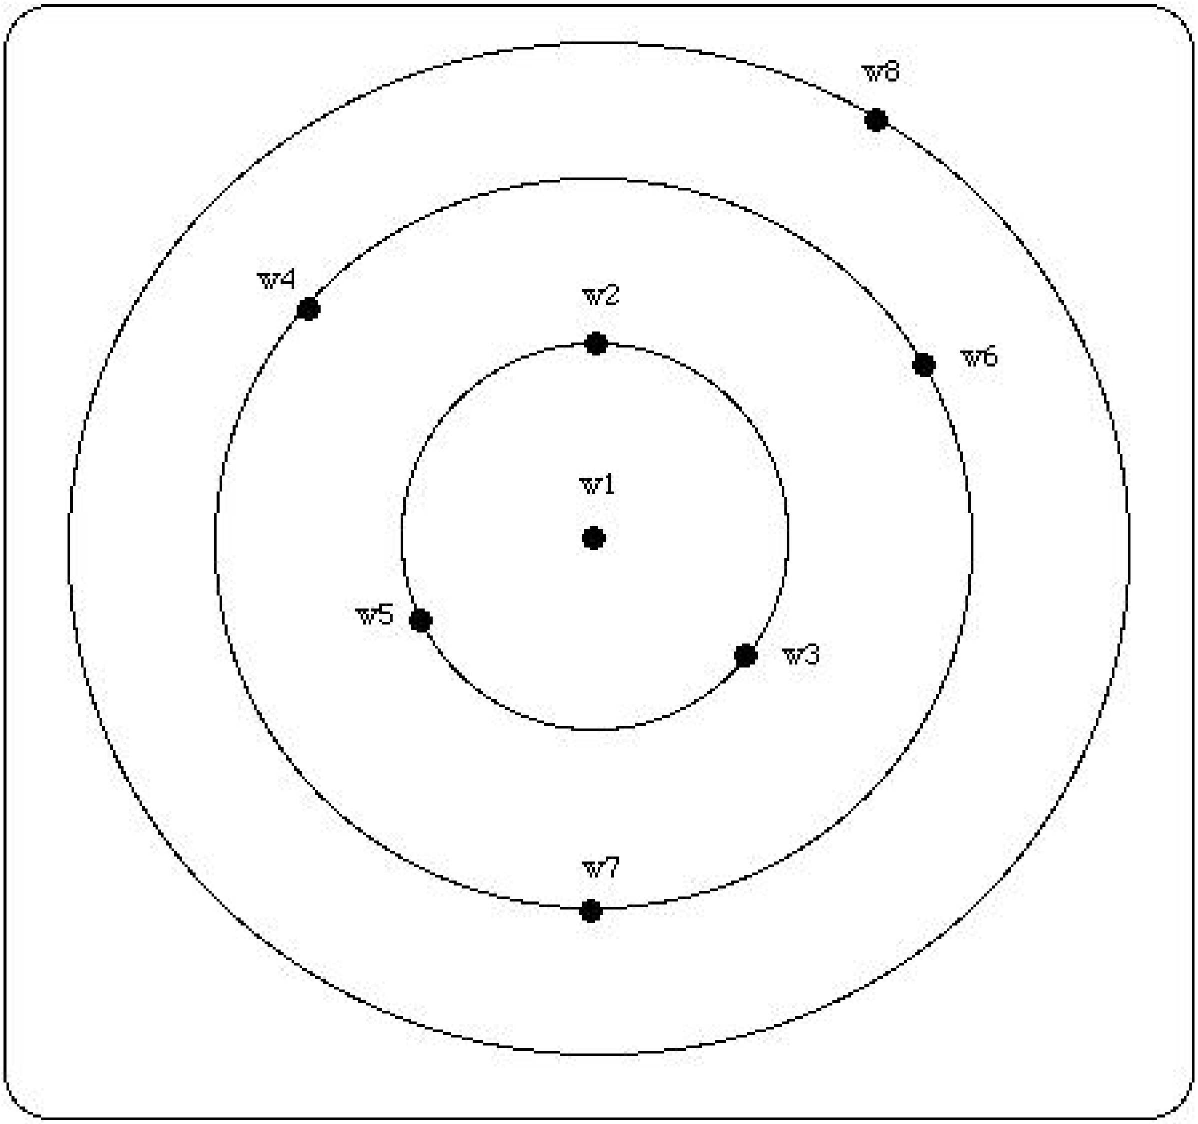

Diagram 6: Similarity circles for the weather space

Those worlds orbiting on the sphere n are of distance n from the actual world. Now that we have numbers associated we can do something a little more ambitious than the partial ordering induced by Hilpinen's proposal. A numerical measure can be defined as some function of distances, from the actual world, of worlds in the range of a proposition. One particularly simple proposal is to take the average distance of worlds from the actual world. This is tantamount to measuring the distance from actuality of the “center of gravity” of the proposition.

This idea of averaging delivers all of the particular judgements we used above to motivate Hilpinen's proposal, but in conjunction with the metric it delivers more comparisons. For example, we have the following sample propositions in descending order of truthlikeness:

Truth Value	Proposition	Distance
true	*h&r&w*	0

true	*h*&*r*	0.5
false	*h*&*r*&~w	1.0
true	*h*	1.3
false	*h*&~*r*	1.5
false	~*h*	1.7
false	~*h*&~*r*&*w*	2.0
false	~*h*&~*r*	2.5
false	~*h*&~*r*&~*w*	3.0

So far these results look quite pleasing. Propositions are closer to the truth the more they get the basic weather traits right, further away the more mistakes they make. A false proposition may be made either worse or better by strengthening (~*w* is the same distance from the Truth as ~*h*; *h*&*r*&~*w* is better than ~*w* while ~*h*&~*r*&~*w* is worse). A false proposition (like *h*&*r*&~*w*) can be closer to the truth than some true propositions (like *h*).

But a number of problems immediately arise. First, the proposal embodies presuppositions of equal weight: both for basic states (in the distance metric on worlds) and for worlds (in the averaging procedure). These simplifications can be easily relaxed. We can weight the different factors according to their importance for the purposes of similarity, and we can clearly take a weighted average rather than a straight average. More importantly, some of the apparently pleasing general features of Hilpinen's account are violated. We can find pairs of true propositions such that the stronger is further from the truth. The tautology is not the true proposition furthest from the Truth (Popper 1976).

Truth Value	**Proposition**	**Distance**
true	*h* ∨ ~*r* ∨ *w*	1.4
true	*h* ∨ ~*r*	1.5
true	*h* ∨ ~*h*	1.5

In deciding how to proceed here we confront a methodological problem. The methodology exemplified by Tichý is very much bottom-up. For the purposes of deciding between rival accounts it takes the intuitive data very seriously . Popper, and Popperians like Miller, take a far more top-down approach. They are suspicious of folk intuitions, and consider themselves to be in the business of constructing a new concept rather than explicating an existing one. They do place enormous weight on certain plausible general principles, largely those that fit in with other principles of their overall theory of science: like the

principle that strength is a virtue and that the stronger of two true theories is the closer to the Truth. A third approach, one which lies between these two extremes, is that of reflective equilibrium. This recognizes the claims of both intuitive judgements on low-level cases, and plausible high-level principles, and enjoins us to bring principle and judgement into equilibrium, possibly by tinkering with both. Neither intuitive low-level judgements nor plausible high-level principles are given advance priority. The protagonist in the truthlikeness debate who argues most consistently for this approach is Niiniluoto.

How does this impact on the current dispute? Consider a different space of possibilities, generated by a single magnitude like the number of the planets (N). For the sake of the argument let's agree that N is in fact 9 and that the further n is from 9, the further the proposition that N=n from the Truth. Consider three sets of propositions. In the left-hand column we have a sequence of false propositions which, intuitively, decrease in truthlikeness while increasing in strength. In the middle column we have a sequence of corresponding true propositions, in each case the strongest true consequence of its false counterpart on the left (Popper's “truth content”). Again members of this sequence steadily increase in strength. Finally on the right we have another column of falsehoods. These are also steadily increasing in strength, and like the left-hand falsehoods, seem also to be decreasing in truthlikeness.

Falsehood (1)	Strongest True Consequence	Falsehood (2)
11 ≤ N ≤ 20	N=9 or 11 ≤ N ≤ 20	N=10 or 11 ≤ N ≤ 20
12 ≤ N ≤ 20	N=9 or 12 ≤ N ≤ 20	N=10 or 12 ≤ N ≤ 20
……	……	……
19 ≤ N ≤ 20	N=9 or 19 ≤ N ≤ 20	N=10 or 19 ≤ N ≤ 20
N = 20	N=9 or N = 20	N=10 or N = 20

Judgements about the closeness of the true propositions to the truth may be less clear than are intuitions about their left-hand counterparts. However, it would seem highly incongruous to judge the truths to be steadily increasing in truthlikeness, while the falsehoods on the right, minimally different in content, steadily decrease in truthlikeness. So both the bottom-up approach and reflective equilibrium suggest that all three are sequences of steadily increasing strength combined with steadily decreasing truthlikeness. And that is enough to overturn Popper's claim that amongst true theories strength and truthlikeness covary. This removes an objection to averaging (or weighted averaging), but does not settle the issue in its favor, for there may still be other more plausible counterexamples to averaging that we have not considered.

5. Generalizing the Approach

The similarity approach faces two obstacles, both of which have analogues in the history of the

development of logical probability. The first is the difficulty of defining a plausible distance measure on spaces of complex worlds. Simple finite examples are all very nice for the purposes of illustration, but what we want is some indication that this is not a special case. The second has been dubbed the problem of translation-invariance. A measure of truthlikeness should be invariant under translations into essentially equivalent languages. This requirement simply reflects the fact that closeness to the truth is a semantic, not a syntactic, affair. David Miller has argue that any account which captures low-level intuitions about similarity must fail this constraint.

One fruitful way of generalizing the simple idea to complex spaces involves cutting such spaces down into finite chunks. This can be done in various ways, but one promising idea (Tichý, 1974, Niiniluoto 1976) is to make use of a certain kind of normal form -- Hintikka's *distributive normal forms* (Hintikka 1963). Constituents correspond to propositional maximal conjunctions. Hintikka defined what he called constituents, which, like maximal conjunctions, are jointly exhaustive and mutually exclusive. Constituents lay out, in a very perspicuous manner, all the different ways individuals can be related. For example, Every sentence in a first-order language comes with a certain *depth* -- the number of embedded quantifiers required to formulate it. So, for example, (1) is a depth-1 sentence; (2) is depth-2; and (3) is depth-3.

> (1) Everyone loves himself.
> (2) Everyone loves another.
> (3) Everyone who loves another loves the other's lovers.

We could call a proposition *depth-d* if the shallowest depth at which it can be expressed is *d*. What Hintikka showed is that every depth-*d* proposition can be expressed by a disjunction of depth-*d* constituents. Constituents can be represented as finite tree-structures, the nodes of which are like straightforward conjunctions of atomic states. Consequently, if we can measure distance between such trees we will be well down the path of measuring the truthlikeness of depth-d propositions: it will be some function of the distance of constituents in its normal form from the true depth-d constituent.

This program has proved flexible and fruitful, delivering a wide range of intuitively appealing results in simple first-order cases. Further, the general idea can be extended in a number of different directions: to higher-order languages and to spaces based on functions rather than properties.

6. Translation Invariance

The single most influential argument against the likeness approach is the charge that it is not translation invariant (Miller 1974a, 1975 a, 1976). Early formulations of the approach (Tichý 1974, 1976) proceeded in terms of syntactic entities -- sentences, predicates, distributive normal forms and the like. The question naturally arises, then, whether we obtain the same measures if all the sentences are translated into an essentially equivalent language -- one capable of expressing the same propositions with a different set of primitive predicates.

Take our simple weather-framework above. This trafficks in three primitives -- *hot*, *rainy*, and *windy* Suppose, however, that we define the following two new weather conditions:

minnesotan $=_{\text{df}}$ hot if and only if rainy

arizonan $=_{\text{df}}$ hot if and only if windy

Now it appears as though we can describe the same sets of weather states in an *h-m-a*-ese based on these conditions.

	***h-r-w*-ese**	***h-m-a*-ese**
T	*h&r&w*	*h&m&a*
A	*~h&r&w*	*~h&~m&~a*
B	*~h&~r&w*	*~h&m&~a*
C	*~h&~r&~w*	*~h&m&a*

If **T** is the truth about the weather then theory **A**, in *h-r-w*-ese, seems to make just one error concerning the original weather states, while **B** makes two and **C** makes three. However, if we express these two theories in *h-m-a*-ese however, then this is reversed: **A** appears to make three errors and **B** still makes two and **C** makes only one error. But that means the account makes truthlikeness, unlike truth, radically language-relative.

There are two live responses to this criticism. But before detailing them, note a dead one: the similarity theorist cannot object that *h-m-a* somehow logically different from *h-r-w*, on the grounds that the primitives of the latter are essentially biconditional whereas the primitives of the former are not. This is because there is a perfect symmetry between the two. Starting within *h-m-a*-ese we can arrive at the original primitives by exactly analogous definitions:

rainy $=_{\text{df}}$ hot if and only if minnesotan
windy $=_{\text{df}}$ hot if and only if arizonan

Thus if we are going to object to *h-m-a*-ese it will have to be on other than purely logical grounds.

Firstly, then, the similarity theorist could maintain that certain predicates (presumably “hot”, “rainy” and “windy”) are primitive in some absolute, realist, sense. Such predicates “carve reality at the joints” whereas others (like “minnesotan” and “arizonan”) are gerrymandered affairs. With the demise of predicate nominalism as a viable account of properties and relations this approach is not as unattractive

as it might have seemed in the middle of the last century. Realism about universals is certainly on the rise. While this version of realism presupposes a sparse theory of properties -- that is to say, it is not the case that to every definable predicate there corresponds a genuine universal -- such theories have been championed both by those doing traditional a priori metaphysics of properties (e.g. Bealer 1982) as well as those who favor or more empiricist, scientifically informed approach (e.g. Armstrong 1978, Tooley 1977). According to Armstrong, for example, which predicates pick out genuine universals is a matter for developed science. The primitive predicates of our best fundamental physical theory will give us our best guess at what the genuine universals in nature are. They might be predicates like electron or mass, or more likely something even more abstruse and remote from the phenomena -- like the primitives of String Theory.

One apparently powerful objection to this realist solution is that it would render the task of empirically estimating degree of truthlikeness completely hopeless. If we know a priori which primitives should be used in the computation of distances between theories it will be difficult to estimate truthlikeness, but not impossible. For example, we might compute the distance of a theory from the various possibilities for the truth, and then make a weighted average, weighting each possible true theory by its probability on the evidence. That would be the credence-mean estimate of truthlikeness. However, if we don't know which features should count towards the computation of similarities and distances then we cannot even get off first base.

To see this consider our simple weather frameworks. Suppose that all I learn is that it is rainy. Do I thereby some grounds for thinking **A** is closer to the truth than **B**? I would if I also knew that *h*-*r*-*w*-ese is the language for calculating distances. For then whatever the truth is, **A** makes one fewer mistake than **B** makes. **A** gets it right on the rain factor, while **B** doesn't, and they must score the same on the other two factors whatever the truth of the matter. But if we switch to *h*-*m*-*a*-ese then **A**'s epistemic superiority is no longer guaranteed. If, for example, **T** is the truth then **B** will be closer to the truth than **A**. That's because in the *h*-*m*-*a* framework raininess as such doesn't count in favor or against the truthlikeness of a proposition.

However, this objection fails if there can be empirical indicators of which conditions are the genuine ones, the ones that carve reality at the joints. Obviously the framework would have to contain more than just *h*, *m* and *a*. It would have to contain resources for describing the states that indicate whether these were genuine primitives. Maybe whether they enter into genuine causal relations will be important, for example. Once we can distribute probabilities over the various candidates for the real universals, then we can use those probabilities to weight the various possible distances which a hypothesis might be from any given theory.

The second live response is both more modest and more radical. It is more modest in that it is not hostage to the objective priority of a particular conceptual scheme, whether that priority is accessed a priori or a posteriori. It is more radical in that it denies a premise of the invariance argument that at first blush is apparently obvious. It denies the equivalence of the two conceptual schemes. It denies that *h*&*r*&*w*, for example, expresses the very same proposition as *h*&*m*r&*a* expresses. If we deny translatability then we can grant the invariance principle, and grant the judgements of distance in both cases, but remain

untroubled. There is no contradiction. (Tichý 1978,, Oddie 1986).

At first blush this seems truly desperate. Haven't the respective conditions been defined in such a way that they are simple equivalent by fiat? That would, of course, be the case if m and a had been introduced as defined terms into *h-r-w*. But if that were the intention then the similarity theorist could retort that the calculation of distances should proceed in terms of the primitives, not the introduced terms. However that is not the only way the argument can be read. We are asked to contemplate two partially overlapping sequences of conditions, and two spaces of possibilities generated by those two sequences. We can thus think of each possibility as a point in a simple three dimensional space. These points are ordered triples of 0s and 1s, the nth entry being a 0 if the *n*th condition is satisfied and 1 if it isn't. Thinking of possibilities in this way, we already have rudimentary geometrical features generated simply by the selection of generating conditions. Points are adjacent if the differ on only one dimension. A path is a sequence of adjacent points. A point *q* is between two points *p* and *r* if *q* lies on a shortest path from *p* to *r*. A region of possibility space is convex if it is closed under the betweeness relation -- anything between two points in the region is also in the region.

Evidently we have two spaces of possibilities, S1 and S2, and the question now arises whether a sentence interpreted over one of these spaces expresses the very same thing as any sentence interpreted over the other. Does *h*&*r*&*w* express the same thing as *h*&*m*&*a*? *h*&*r*&*w* expresses (the singleton of) u1 (which is the entity <1,1,1> in S1 or <1,1,1>$_{S1}$) and *h*&*m*&*a* expresses v1 (the entity <1,1,1>$_{S2}$). ~*h*&*r*&*w* expresses u2 (<0,1,1>$_{S1}$), a point adjacent to that expressed by *h*&*r*&*w*. However ~*h*&~*m*&~*a* expresses v8 (<0,0,0>$_{S2}$), which is not adjacent to v1 (<1,1,1>$_{S2}$). So now we can construct a simple proof that the two sentences do not express the same thing.

> u1 is adjacent to u2
>
> v1 is not adjacent to v8

therefore

> either u1 is not identical to v1 or u2 is not identical v8.

therefore

> Either *h*&*r*&*w* and *h*&*m*&*a* do not express the same thing, or
>
> ~*h*&*r*&*w* and ~*h*&~*m*&~*a* do not express the same thing.

Thus at least one of the two required intertranslatability claims fails, and *h-r-w*-ese is not intertranslatable with *h-m-a*-ese. The important point here is that a space of possibilities already comes with a structure and the points in such a space cannot be individuated without reference to rest of the space and its

structure. The identity of a possibility is bound up with its geometrical relations to other possibilities. Different relations, different possibilities.

This idea meshes well with recent work on conceptual spaces in Gärdenfors [2000]. Gärdenfors is concerned both with the semantics and the nature of genuine properties, and his bold and simple hypothesis is that properties carve out convex regions of an n-dimensional quality space. He supports this hypothesis with an impressive array of logical, linguistic and empirical data. (Looking back at our little spaces above it is not hard to see that the convex regions are those that correspond to the generating (or atomic) conditions and conjunctions of those. See Oddie 1987a.) While is dealing with properties it is not hard to see that similar considerations apply, since propositions can be regarded as 0-ary properties.

Ultimately, however, this response seems less than entirely satisfactory by itself. If the choice of a conceptual space is just a matter of taste then we may be forced to embrace a radical kind of incommensurability. Those who talk *h-r-w*-ese and conjecture ~*h*&*r*&*w* on the basis of the available evidence will be close to the truth. Those who talk *h-m-a*-ese while exposed to the "same" circumstances would presumably conjecture ~*h*&~*m*&~*a* on the basis of the "same" evidence (or the corresponding evidence that they gather). If in fact *h*&*r*&*w* is the truth (in *h-r-w*-ese) then the *h-r-w* weather researchers will be close to the truth. But the *h-m-a* researchers will be very far from the truth. This may not be an explicit contradiction, but it should be worrying. Realists started out with the ambition of defending a concept of truthlikeness which would enable them to embrace both fallibilism and optimism. But what they have ended up with is something that smacks of rather too radical a version of the incommensurability of competing conceptual frameworks. Presumably the realist will need to add that some conceptual schemes really are better than others. Some "carve reality at the joints" and others don't. But is that something the realist will be reluctant to affirm?

Quantum Mechanics

Quantum mechanics is, at least at first glance and at least in part, a mathematical machine for predicting the behaviors of microscopic particles -- or, at least, of the measuring instruments we use to explore those behaviors -- and in that capacity, it is spectacularly successful: in terms of power and precision, head and shoulders above any theory we have ever had. Mathematically, the theory is well understood; we know what its parts are, how they are put together, and why, in the mechanical sense (i.e., in a sense that can be answered by describing the internal grinding of gear against gear), the whole thing performs the way it does, how the information that gets fed in at one end is converted into what comes out the other. The question of what kind of a world it describes, however, is controversial; there is very little agreement, among physicists and among philosophers, about what the world *is like* according to quantum mechanics. Minimally interpreted, the theory describes a set of facts about the way the microscopic world impinges on the macroscopic one, how it effects our measuring instruments, described in everyday language or the language of classical mechanics. Disagreement centers on the question of what a microscopic world, which affects our apparatuses in the prescribed manner, is, or even could be, like *intrinsically*; or how those apparatuses could themselves be built out of microscopic parts of the sort the theory describes.[1]

That is what an interpretation of the theory would provide: a proper account of what the world is like according to quantum mechanics, intrinsically and from the bottom up. The problems with giving an interpretation (not just a comforting, homey sort of interpretation, i.e., not just an interpretation according to which the world isn't too different from the familiar world of common sense, but any interpretation at all) are dealt with in other sections of this encyclopedia. Here, we are concerned only with the mathematical heart of the theory, the theory in its capacity as a mathematical machine, and -- whatever is true of the rest of it -- *this* part of the theory makes exquisitely good sense.

1. Terminology

Physical systems are divided into **types** according to their unchanging (or ‘state-independent’) properties, and the **state** of a system at a time consists of a complete specification of those of its properties that change with time (its ‘state-dependent’ properties). To give a complete description of a system, then, we need to say what type of system it is and what its state is at each moment in its history.

A **physical quantity** is a mutually exclusive and jointly exhaustive family of physical properties (for those who know this way of talking, it is a family of properties with the structure of the cells in a partition). Knowing what kinds of values a quantity takes can tell us a great deal about the relations among the properties of which it is composed. The values of a bivalent quantity, for instance, form a set with two members; the values of a real-valued quantity form a set with the structure of the real numbers. This is a special case of something we will see again and again, *viz.*, that knowing what kind of mathematical objects represent the elements in some set (here, the values of a physical quantity; later, the states that a system can assume, or the quantities pertaining to it) tells us a very great deal (indeed, arguably, all there is to know) about the relations among them.

In quantum mechanical contexts, the term ‘**observable**’ is used interchangeably with ‘physical quantity’, and should be treated as a technical term with the same meaning. It is no accident that the early developers of the theory chose the term, but the choice was made for reasons that are not, nowadays, generally accepted. The **state-space** of a system is the space formed by the set of its possible states,[2] i.e., the physically possible ways of combining the values of quantities that characterize it internally. In classical theories, a set of quantities which forms a supervenience basis for the rest is typically designated as ‘basic’ or ‘fundamental’, and, since any mathematically possible way of combining their values is a physical possibility, the state-space can be obtained by simply taking these as coordinates.[3] So, for instance, the state-space of a classical mechanical system composed of n particles, obtained by specifying the values of 6n real-valued quantities - three components of position, and three of momentum for each particle in the system - is a 6n-dimensional coordinate space. Each possible state of such a system corresponds to a point in the space, and each point in the space corresponds to a possible state of such a system. The situation is a little different in quantum mechanics, where there are mathematically describable ways of combining the values of the quantities that don't represent physically possible states. As we will see, the state-spaces of quantum mechanics are special kinds of vector spaces, known as Hilbert spaces, and they have more internal structure than their classical counterparts.

A **structure** is a set of elements on which certain operations and relations are defined, a **mathematical structure** is just a structure in which the elements are mathematical objects (numbers, sets, vectors) and the operations mathematical ones, and a **model** is a mathematical structure used to represent some physically significant structure in the world.

The heart and soul of quantum mechanics is contained in the Hilbert spaces that represent the state-spaces of quantum mechanical systems. The internal relations among states and quantities, and

everything this entails about the ways quantum mechanical systems behave, are all woven into the structure of these spaces, embodied in the relations among the mathematical objects which represent them.[4] This means that understanding what a system is like according to quantum mechanics is inseparable from familiarity with the internal structure of those spaces. Know your way around Hilbert space, and become familiar with the dynamical laws that describe the paths that vectors travel through it, and you know everything there is to know, in the terms provided by the theory, about the systems that it describes.

By ‘know your way around’ Hilbert space, I mean something more than possess a description or a map of it; anybody who has a quantum mechanics textbook on their shelf has that. I mean know your way around it in the way you know your way around the city in which you live. This is a practical kind of knowledge that comes in degrees and it is best acquired by learning to solve problems of the form: How do I get from A to B? Can I get there without passing through C? And what is the shortest route? Graduate students in physics spend long years gaining familiarity with the nooks and crannies of Hilbert space, locating familiar landmarks, treading its beaten paths, learning where secret passages and dead ends lie, and developing a sense of the overall lay of the land. They learn how to navigate Hilbert space in the way a cab driver learns to navigate his city.

How much of this kind of knowledge is needed to approach the philosophical problems associated with the theory? In the beginning, not very much: just the most general facts about the geometry of the landscape (which is, in any case, unlike that of most cities, beautifully organized), and the paths that (the vectors representing the states of) systems travel through them. That is what will be introduced here: first a bit of easy math, and then, in a nutshell, the theory.

2. Mathematics

Vectors and vector spaces

A **vector** A, written ‘|A>’, is a mathematical object characterized by a length, |A|, and a direction. A normalized vector is a vector of length 1; i.e., |A| = 1. Vectors can be added together, multiplied by constants (including complex numbers), and multiplied together. Vector addition maps any pair of vectors onto another vector, specifically, the one you get by moving the second vector so that it's tail coincides with the tip of the first, without altering the length or direction of either, and then joining the tail of the first to the tip of the second. This addition rule is known as the parallelogram law. So, for example, adding vectors |A> and |B> yields vector |C> (= |A> + |B>) as in Figure 1:

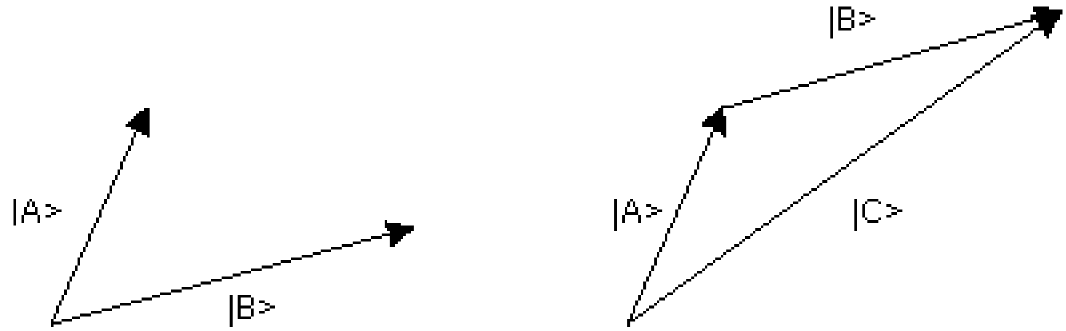

Figure 1: Vector Addition

Multiplying a vector |A> by *n*, where *n* is a constant, gives a vector which is the same direction as |A> but whose length is *n* times |A>'s length.

In a real vector space, the (inner or dot) product of a pair of vectors |A> and |B>, written ‘<A|B>’ is a scalar equal to the product of their lengths (or ‘norms’) times the cosine of the angle, θ, between them:

$$<A|B> = |A|\ |B| \cos \theta$$

Let $|A_1>$ and $|A_2>$ be vectors of length 1 ("unit vectors") such that $<A_1|A_2> = 0$. (So the angle between these two unit vectors must be 90 degrees.) Then we can represent an arbitrary vector |B> in terms of our unit vectors as follows:

$$|B> = b_1|A_1> + b_2|A_2>$$

For example, here is a graph which shows how |B> can be represented as the sum of the two unit vectors $|A_1>$ and $|A_2>$:

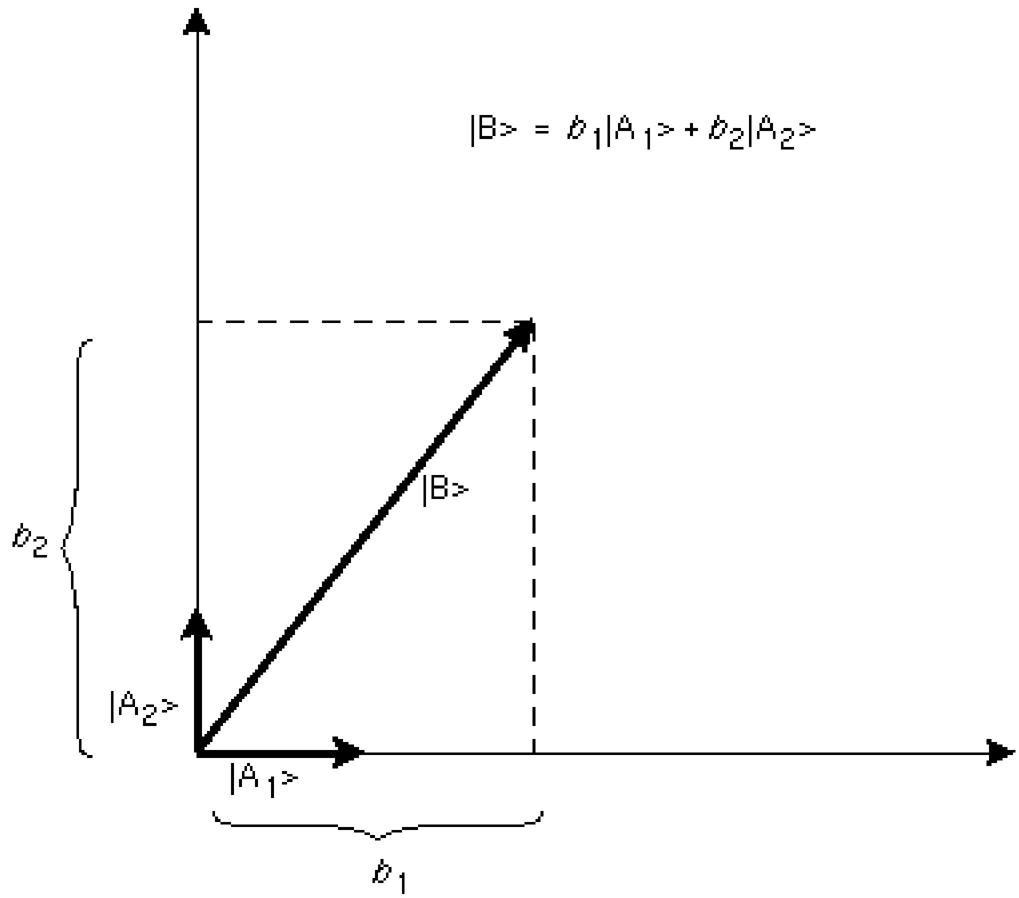

Figure 2: Representing |B> by Vector Addition of Unit Vectors

Now the definition of the inner product <A|B> has to be modified to apply to complex spaces. Let *c** be the complex conjugate of *c*. (When *c* is a complex number of the form *a* ± *bi*, then the complex conjugate *c** of *c* is defined as follows:

$[a + bi]^* = a - bi$
$[a - bi]^* = a + bi$

So, for all complex numbers *c*, [*c**]* = *c*, but *c** = *c* just in case *c* is real.) Now definition of the inner product of |A> and |B> for complex spaces can be given in terms of the conjugates of complex coefficients as follows. Where $|A_1>$ and $|A_2>$ are the unit vectors described earlier, $|A> = a_1|A_1> + a_2|A_2>$ and $|B> = b_1|A_1> + b_2|A_2>$, then

$<A|B> = (a_1^*)(b_1) + (a_2^*)(b_2)$

The most general and abstract notion of an inner product, of which we've now defined two special cases, is as follows. <A|B> is an inner product on a vector space V just in case

(i) $<A|A> = |A|^2$, and <A|A>=0 if and only if A=0

(ii) $<B|A> = <A|B>^*$

(iii) $<B|A+C> = <B|A> + <B|C>$.

It follows from this that

(i) the length of $|A>$ is the square root of inner product of $|A>$ with itself, i.e.,

$$|A| = \sqrt{<A|A>},$$

and

(ii) $|A>$ and $|B>$ are mutually perpendicular, or **orthogonal,** if, and only if, $<A|B> = 0$.

A **vector space** is a set of vectors closed under addition, and multiplication by constants, **an inner product space** is a vector space on which the operation of vector multiplication has been defined, and the **dimension** of such a space is the maximum number of nonzero, mutually orthogonal vectors it contains.

Any collection of N mutually orthogonal vectors of length 1 in an N-dimensional vector space constitutes an **orthonormal basis** for that space. Let $|A_1>, \ldots , |A_N>$ be such a collection of unit vectors. Then every vector in the space can be expressed as a sum of the form:

$$|B> = b_1|A_1> + b_2|A_2> + \ldots + b_N|A_N>,$$

where $b_i = <B|A_i>$. The b_i's here are known as B's **expansion coefficients** in the A-basis.[5]

Notice that:

(i) for all vectors A, B, and C in a given space,

$$<A|B+C> = <A|B> + <A|C>$$

(ii) for any vectors M and Q, expressed in terms of the A-basis,

$$|M> + |Q> = (m_1 + q_1)|A_1> + (m_2 + q_2)|A_2> + \ldots + (m_N + q_N)|A_N>,$$

and

$$<M|Q> = m_1q_1 + m_2q_2 + \ldots + m_nq_n$$

There is another way of writing vectors, namely by writing their expansion coefficients (relative to a given basis) in a column, like so:

$$|Q> = \begin{bmatrix} q_1 \\ q_2 \end{bmatrix}$$

where $q_i = <Q|A_i>$ and the A_i are the chosen basis vectors.

When we are dealing with vector spaces of infinite dimension, since we can't write the whole column of expansion coefficients needed to pick out a vector since it would have to be infinitely long, so instead we write down the function (called the ‘wave function’ for Q, usually represented $\psi(i)$) which has those coefficients as values. We write down, that is, the function:

$$\psi(i) = q_i = <Q|A_i>$$

Given any vector in, and any basis for, a vector space, we can obtain the wave-function of the vector in that basis; and given a wave-function for a vector, in a particular basis, we can construct the vector whose wave-function it is. Since it turns out that most of the important operations on vectors correspond to simple algebraic operations on their wave-functions, this is the usual way to represent state-vectors.

When a pair of physical systems interact, they form a composite system, and, in quantum mechanics as in classical mechanics, there is a rule for constructing the state-space of a composite system from those of its components, a rule that tells us how to obtain, from the state-spaces, H_A and H_B for A and B, respectively, the state-space -- called the ‘tensor product’ of H_A and H_B, and written $H_A \otimes H_B$ -- of the pair. There are two important things about the rule; first, so long as H_A and H_B are Hilbert spaces, $H_A \otimes H_B$ will be as well, and second, there are some facts about the way $H_A \otimes H_B$ relates to H_A and H_B, that have surprising consequences for the relations between the complex system and its parts. In particular, it turns out that the state of a composite system is not uniquely defined by those of its components. What this means, or at least what it appears to mean, is that there are, according to quantum mechanics, facts about composite systems (and not just facts about their spatial configuration) that don't supervene on facts about their components; it means that there are facts about systems as wholes that don't supervene on facts about their parts and the way those parts are arranged in space. The significance of this feature of the theory cannot be overplayed; it is, in one way or another, implicated in most of its most difficult problems.

In a little more detail: if $\{v_i^A\}$ is an orthonormal basis for H_A and $\{u_j^B\}$ is an orthonormal basis for H_B, then the set of pairs (v_i^A, u_j^B) is taken to form an orthonormal basis for the tensor product space $H_A \otimes H_B$. The notation $v_i^A \otimes u_j^B$ is used for the pair (v_i^A, u_j^B), and inner product on $H_A \otimes H_B$ is defined as:[6]

$$<v_i^A \otimes u_m^B \mid v_j^A \otimes u_n^B> \; = \; <v_i^A \mid v_j^A> \; <u_m^B \mid u_n^B>$$

It is a result of this construction that although every vector in $H_A \otimes H_B$ is a linear sum of vectors expressible in the form $v^A \otimes u^B$, not every vector in the space is itself expressible in that form, and it turns out that

(i) any composite state defines uniquely the states of its components.

(ii) if the states of A and B are pure (i.e., representable by vectors v^A and u^B, respectively), then the state of (A+B) is pure and represented by $v^A \otimes u^B$, and

(iii) if the state of (A+B) is pure and expressible in the form $v^A \otimes u^B$, then the states of A and B are pure, but

(iv) if the states of A and B are not pure, i.e., if they are mixed states (these are defined below), they do not uniquely define the state of (A+B); in particular, it may be a pure state not expressible in the form $v^A \otimes u^B$.

Operators

An **operator** O is a mapping of a vector space onto itself; it takes any vector |B> in a space onto another vector |B′> also in the space; O|B> = |B′>. **Linear operators** are operators that have the following properties:

(i) O(|A> + |B>) = O|A> + O|B>, and

(ii) O(*c*|A>) = *c*(O|A>).

Just as any vector in an N-dimensional space can be represented by a column of N numbers, relative to a choice of basis for the space, any linear operator on the space can be represented in a column notation by N^2 numbers:

$$O = \begin{bmatrix} O_{11} & O_{12} \\ O_{21} & O_{22} \end{bmatrix}$$

where $O_{ij} = < A_i \mid O|A_j>$ and the $|A_N>$ are the basis vectors of the space. The effect of the linear operator O on the vector B is, then, given by

O|B>=

$$= \begin{bmatrix} O_{11} & O_{12} \\ O_{21} & O_{22} \end{bmatrix} \times \begin{bmatrix} b_1 \\ b_2 \end{bmatrix}$$

$$= \begin{bmatrix} (O_{11}b_1 + O_{12}b_2) \\ (O_{21}b_1 + O_{22}b_2) \end{bmatrix}$$

$$= (O_{11}b_1 + O_{12}b_2)|A_1\rangle + (O_{21}b_1 + O_{22}b_2)|A_2\rangle$$

$$= |B'\rangle$$

Two more definitions before we can say what Hilbert spaces are, and then we can turn to quantum mechanics. |B> is an **eigenvector** of O with eigenvalue *a* if, and only if, O|B> = *a*|B>. Different operators can have different eigenvectors, but the eigenvector/operator relation depends only on the operator and vectors in question, and not on the particular basis in which they are expressed; the eigenvector/operator relation is, that is to say, invariant under change of basis. **Hermitean operators** are linear operators, which have only real eigenvalues.

A **Hilbert space**, finally, is a vector space on which an inner product is defined, and which is complete, i.e., which is such that any Cauchy sequence of vectors in the space converges to a vector in the space. All finite-dimensional inner product spaces are complete, and I will restrict myself to these. The infinite case involves some complications that are not fruitfully entered into at this stage.

3. Quantum Mechanics

Four basic principles of quantum mechanics are:

3.1 Physical States

Every physical system is associated with a Hilbert Space, every unit vector in the space corresponds to a possible pure state of the system, and every possible pure state, to some vector in the space.[7] In standard texts on quantum mechanics, the vector is represented by a function known as the wave-function, or ψ-function.

3.2 Physical Quantities

Hermitian operators in the Hilbert space associated with a system represent physical quantities, and their eigenvalues represent the possible results of measurements of those quantities.

3.3 Composition

The Hilbert space associated with a complex system is the tensor product of those associated with the simple systems (in the standard, non-relativistic, theory: the individual particles) of which it is composed.

3.4 Dynamics

a. *Contexts of type 1*: Given the state of a system at t and the forces and constraints to which it is subject, there is an equation, '**Schrödinger's equation**', that gives the state at any other time U|v_t> → |v_t′>.[8] The important properties of U for our purposes are that it is **deterministic,** which is to say that it takes the state of a system at one time into a unique state at any other, and it is **linear**, which is to say that if it takes a state |A> onto the state |A′>, and it takes the state |B> onto the state |B′>, then it takes any state of the form α|A> + β|B> onto the state α|A′> + β|B′>.

b. *Contexts of type 2* ("Measurement Contexts"):[9] Carrying out a "measurement" of an observable B on a system in a state |A> has the effect of collapsing the system into a B-eigenstate corresponding to the eigenvalue observed. This is known as the **Collapse Postulate**. Which *particular* B-eigenstate it collapses into is a matter of probability, and the probabilities are given by a rule known as **Born's Rule**:

$$prob(b_i) = |\langle A|B=b_i\rangle|^2.$$

There are two important points to note about these two kinds of contexts:

- The distinction between contexts of type 1 and 2 remains to be made out in quantum mechanical terms; nobody has managed to say in a completely satisfactory way, in the terms provided by the theory, which contexts are measurement contexts, and
- Even if the distinction is made out, it is an open interpretive question whether there *are* contexts of type 2; i.e., it is an open interpretive question whether there are any contexts in which systems are governed by a dynamical rule *other* than Schrödinger's equation.

4. Structures on Hilbert Space

I remarked above that in the same way that all the information we have about the relations between locations in a city is embodied in the spatial relations between the points on a map which represent them, all of the information that we have about the internal relations among (and between) states and quantities in quantum mechanics is embodied in the mathematical relations among the vectors and operators which represent them.[10] From a mathematical point of view, what really distinguishes quantum mechanics from its classical predecessors is that states and quantities have a richer structure; they form families with a more interesting network of relations among their members.

All of the physically consequential features of the behaviors of quantum mechanical systems are consequences of mathematical properties of those relations, and the most important of them are easily summarized:

> (P1) Any way of adding vectors in a Hilbert space or multiplying them by scalars will yield a vector that is also in the space. In the case that the vector is normalized, it will, from (3.1), represent a possible state of the system, and in the event that it is the sum of a pair of eigenvectors of an observable B with distinct eigenvalues, it will not itself be an eigenvector of B, but will be associated, from (3.4b), with a set of probabilities for showing one or another result in B-measurements.
>
> (P2) For any Hermitian operator on a Hilbert space, there are others, on the same space, with which it doesn't share a full set of eigenvectors; indeed, it is easy to show that there are other such operators with which it has *no* eigenvectors in common.

If we make a couple of additional interpretive assumptions, we can say more. Assume, for instance, that

> (4.1) Every Hermitian operator on the Hilbert space associated with a system represents a distinct observable, and (hence) every normalized vector, a distinct state, and
>
> (4.2) A system has a value for observable A if, and only if, the vector representing its state is an eigenstate of the A-operator. The value it has, in such a case, is just the eigenvalue associated with that eigenstate.[11]

It follows from (P2), by (3.1), that no quantum mechanical state is an eigenstate of all observables (and indeed that there are observables which have *no* eigenstates in common), and so, by (3.2), that no quantum mechanical system ever has simultaneous values for all of the quantities pertaining to it (and indeed that there are pairs of quantities to which *no* state assigns simultaneous values).

There are Hermitian operators on the tensor product $H_1 \otimes H_2$ of a pair of Hilbert spaces H_1 and H_2 ... In the event that H_1 and H_2 are the state spaces of systems S1 and S2, $H_1 \otimes H_2$ is the state-space of the complex system (S1+S2). It follows from this by (4.1) that there are observables pertaining to (S1+S2) whose values are not determined by the values of observables pertaining to the two individually.

These are all straightforward consequences of taking vectors and operators in Hilbert space to represent, respectively, states and observables, and applying Born's Rule (and later (4.1) and (4.2)), to give empirical meaning to state assignments. That much is perfectly well understood; the real difficulty in understanding quantum mechanics lies in coming to grips with their implications -- physical, metaphysical, and epistemological.

There is one remaining fact about the mathematical structure of the theory that anyone trying to come to an understanding about what it says about the world has to grapple with. It is not a property of Hilbert spaces, this time, but of the dynamics, the rules that describe the trajectories that systems follow through the space. From a physical point of view, it is far more worrisome than anything that has preceded. For, it does much more than present difficulties to someone trying to provide an *interpretation* of the theory, it seems to point either to a logical inconsistency in the theory's foundations.

Suppose that we have a system S and a device S* which measures an observable A on S with values $\{a_1, a_2, a_3 ...\}$. Then there is some state of S* (the ‘ground state’), and some observable B with values $\{b_1, b_2, b_3 ...\}$ pertaining to S* (its ‘pointer observable’, so called because it is whatever plays the role of the pointer on a dial on the front of a schematic measuring instrument in registering the result of the experiment), which are such that, if S* is started in its ground state and interacts in an appropriate way with S, and if the value of A immediately before the interaction is a_1, then B's value immediately thereafter is b_1. If, however, A's value immediately before the interaction is a_2, then B's value afterwards is b_2; if the value of A immediately before the interaction is a_3, then B's value immediately after is b_3, and so on. That is just what it *means* to say that S* measures A. So, if we represent the joint, partial state of S and S* (just the part of it which specifies the value of [A on S & B on S*], the observable whose values correspond to joint assignments of values to the measured observable on S and the pointer observable on S*) by the vector $|A=a_i>_s|B=b_i>_{s*}$, and let "$\rightarrow$" stand in for the dynamical description of the interaction between the two, to say that S* is a measuring instrument for A is to say that the dynamical laws entail that,

$$|A=a_1>_s|B=\text{ground state}>_{s*} \rightarrow |A=a_1>_s|B=b_1>_{s*}$$

$$|A=a_2>_s|B=\text{ground state}>_{s*} \rightarrow |A=a_2>_s|B=b_2>_{s*}$$

$$|A=a_3>_s|B=\text{ground state}>_{s*} \rightarrow |A=a_3>_s|B=b_3>_{s*}$$

and so on.[12]

Intuitively, S* is a measuring instrument for an observable A just in case there is some observable feature of S* (it doesn't matter what, just something whose values can be ascertained by looking at the device), which is correlated with the A-values of systems fed into it in such a way that we can read those values off of S*'s observable state after the interaction. In philosophical parlance, S* is a measuring instrument for A just in case there is some observable feature of S* which *tracks* or *indicates* the A-values of systems with which it interacts in an appropriate way.

Now, it follows from (3.1), above, that there are states of S (too many to count) which are not eigenstates of A, and if we consider what Schrödinger's equation tells us about the joint evolution of S and S* when S is started out in one of these, we find that the state of the pair after interaction is a superposition of

eigenstates of [A on S & B on S*]. It doesn't matter what observable on S is being measured, and it doesn't matter what particular superposition S starts out in; when it is fed into a measuring instrument for that observable, if the interaction is correctly described by Schrödinger's equation, it follows just from the linearity of the U in that equation, the operator that effects the transformation from the earlier to the later state of the pair, that the joint state of S and the apparatus after the interaction is a superposition of eigenstates of this observable on the joint system.

Suppose, for example, that we start S* in its ground state, and S in the state

$$1/\sqrt{2}|A=a_1>_s| + 1/\sqrt{2}|A=a_2>_s$$

It is a consequence of the rules for obtaining the state-space of the composite system that the combined state of the pair is

$$1/\sqrt{2}|A=a_1>_s|B=\text{ground state}>_{s*} + 1/\sqrt{2}|A=a_2>_s|B=\text{ground state}>_{s*}$$

and it follows from the fact that S* is a measuring instrument for A, and the linearity of U that their combined state *after* interaction, is

$$1/\sqrt{2}|A=a_1>_s|B=b_1>_{s*} + 1/\sqrt{2}|A=a_2>_s|B=b_2>_{s*}$$

This, however, is inconsistent with the dynamical rule for contexts of type 2, for the dynamical rule for contexts of type 2 (and if there are any such contexts, *this* is one) entails that the state of the pair after interaction is *either*

$$|A=a_1>_s|B=b_1>_{s*}$$

or

$$|A=a_2>_s|B=b_2>_{s*}$$

Indeed, it entails that there is a precise probability of 1/2 that it will end up in the former, and a probability of 1/2 that it will end up in the latter.

We can try to restore logical consistency by giving up the dynamical rule for contexts of type 2 (or, what amounts to the same thing, by denying that there *are* any such contexts), but then we have the problem of consistency with experience. For it was no mere blunder that that rule was included in the theory; we *know* what a system looks like when it is in an eigenstate of a given observable, and we know *from looking* that the measuring apparatus after measurement is in an eigenstate of the pointer observable. And so we *know* from the outset that if a theory tells us something else about the post-measurement states of

measuring apparatuses, whatever that something else is, it is wrong.

That, in a nutshell, is the Measurement Problem in quantum mechanics; any interpretation of the theory, any detailed story about what the world is like according to quantum mechanics, and in particular those bits of the world in which measurements are going on, has to grapple with it.

Loose Ends

Mixed states are weighted sums of pure states, and they can be used to represent the states of ensembles whose components are in different pure states, or states of individual systems about which we have only partial knowledge. In the first case, the weight attached to a given pure state reflects the size of the component of the ensemble which is in that state (and hence the objective probability that an arbitrary member of the ensemble is); in the second case, they reflect the epistemic probability that the system in question to which the state is assigned is in that state.

If we don't want to lose the distinction between pure and mixed states, we need a way of representing the weighted sum of a set of pure states (equivalently, of the probability functions associated with them) that is different from adding the (suitably weighted) vectors that represent them, and that means that we need either an alternative way of representing mixed states, or a uniform way of representing both pure and mixed states that preserves the distinction between them. There is a kind of operator in Hilbert spaces, called a **density operator**, that serves well in the latter capacity, and it turns out not to be hard to restate everything that has been said about state vectors in terms of density operators. So, even though it is common to speak as though pure states are represented by vectors, the official rule is that states – pure and mixed, alike - are represented in quantum mechanics by density operators.

Although mixed states *can*, as I said, be used to represent our ignorance of the states of systems that are actually in one or another pure state, and although this has seemed to many to be an adequate way of interpreting mixtures in classical contexts, there are serious obstacles to applying it generally to quantum mechanical mixtures. These are left for detailed discussion in the other entries on quantum mechanics in the Encyclopedia.

Everything that has been said about observables, strictly speaking, applies only to the case in which the values of the observable form a discrete set; the mathematical niceties that are needed to generalize it to the case of **continuous observables** are complicated, and raise problems of a more technical nature. These, too, are best left for detailed discussion.

This should be all the initial preparation one needs to *approach* the philosophical discussion of quantum mechanics, but it is only a first step. The more one learns about the relationships among and between vectors and operators in Hilbert space, about how the spaces of simple systems relate to those of complex ones, and about the equation which describes how state-vectors move through the space, the better will be one's appreciation of both the nature and the difficulty of the problems associated with the theory. The funny backwards thing about quantum mechanics, the thing that makes it endlessly absorbing to a

philosopher, is that the more one learns, the harder the problems get.

Stanford Encyclopedia of Philosophy
Notes to Quantum Mechanics

Notes

1. Indeed, when pressed, we find we can't even say explicitly (in the terms provided by the theory, in terms that apply directly to the entities, quantities, and relations of which the world is, by its lights, composed) which systems count as macroscopic (or what would be just as good, which are ‘classical’, which are fit to act as measuring apparatuses, or which interactions count as measurements).

2. It is also sometimes used to refer to a mathematical model that represents that space, a mathematical model that provides a kind of map of the set of possible states.

3.There will, of course, be arbitrariness in the coordinate description of the state-space, thus obtained, precisely as much arbitrariness as there is in the choice of mathematical names for the values of basic quantities.

4. Another way to put this: if you consider the set of states associated with any quantum mechanical system, you would find that it had the structure of the set of vectors in a Hilbert space.

5. Notice the relations between bases and coordinate systems; vectors of norm 1 pointing along the perpendicular coordinate axes of an N-dimensional point space constitute an orthonormal basis for the associated N-dimensional vector space, and there are as many bases for the vector space as possible coordinatizations of the point space.

6.The reader can satisfy herself that since (v_i^A, u_j^B) spans $H_A \otimes H_B$, the equation defines, by linearity, an inner product on the whole space, and also that, since $|v| = 0$ just in case v is the zero vector, it follows that $v^A \otimes 0 = 0 = 0 \otimes u^B$.

7. The correspondence isn't unique; any vectors |A> and @|A> where @ is any complex number of absolute value 1 correspond to the same state. There may be other redundancies; some interpretations, for instance, invoke what are called superselection rules that identify states represented by distinct normalized vectors. (i) is modified below, when mixed states are defined.

8. The equation is usually expressed in the form $i\, dv/dt = \mathbf{H}v$, where v is the system's state vector and **H** the operator representing its energy, but, again, the details aren't immediately important.

9. The quotes are to recommend caution about reading too much of one's ordinary understanding of this

word into its use in quantum mechanics; one usually thinks of measurement as a way of obtaining information about a system, but the only information one takes away from an individual quantum-mechanical ‘measurement’ about the state of the measured system before the interaction is that it was not (or, at least, there is a measure zero probability that it was) in an eigenstate of the measured observable with an eigenvalue other than the one observed. Of course, if the Collapse Postulate is correct, one knows the state of the system after measurement, but if I shoot someone at close range, I can be pretty sure that they are dead afterward; that doesn't make the interaction a measurement of the state of their health.

10. The two are not independent, of course; a system's state is just a specification of the values of those quantities pertaining to it that change over time. Internal relations between a set of elements are relations that supervene on their intrinsic natures; they do not include nomological relations.

11. These are strong assumptions: the first denies the existence of superselection rules, and the second, known as the eigenstate-eigenvalue link, is the principle that defines the orthodox Copenhagen interpretation of the theory. I make them here only to illustrate some of the implications of (P2) in an interpretive context.

12. It is inessential that the reduced state of S after the interaction be what it was beforehand; that is so only in the special case of measurements that leave the value of the measured observable undisturbed.

Bohmian Mechanics

Bohmian mechanics, which is also called the de Broglie-Bohm theory, the pilot-wave model, and the causal interpretation of quantum mechanics, is a version of quantum theory discovered by Louis de Broglie in 1927 and rediscovered by David Bohm in 1952. It is the simplest example of what is often called a hidden variables interpretation of quantum mechanics. In Bohmian mechanics a system of particles is described in part by its wave function, evolving, as usual, according to Schrödinger's equation. However, the wave function provides only a partial description of the system. This description is completed by the specification of the actual positions of the particles. The latter evolve according to the "guiding equation," which expresses the velocities of the particles in terms of the wave function. Thus, in Bohmian mechanics the configuration of a system of particles evolves via a deterministic motion choreographed by the wave function. In particular, when a particle is sent into a two-slit apparatus, the slit through which it passes and where it arrives on the photographic plate are completely determined by its initial position and wave function.

Bohmian mechanics inherits and makes explicit the nonlocality implicit in the notion, common to just about all formulations and interpretations of quantum theory, of a wave function on the configuration space of a many-particle system. It accounts for all of the phenomena governed by nonrelativistic quantum mechanics, from spectral lines and scattering theory to superconductivity, the quantum Hall effect and quantum computing. In particular, the usual measurement postulates of quantum theory, including collapse of the wave function and probabilities given by the absolute square of probability amplitudes, emerge from an analysis of the two equations of motion - Schrödinger's equation and the guiding equation - without the traditional invocation of a special, and somewhat obscure, status for observation.

---

1. The Completeness of the Quantum Mechanical Description

Despite its extraordinary predictive successes, quantum mechanics has, since its inception some seventy years ago, been plagued by conceptual difficulties. The basic problem, plainly put, is this: It is not at all clear what quantum mechanics is about. What, in fact, does quantum mechanics describe?

It might seem, since it is widely agreed that any quantum mechanical system is completely described by its wave function, that quantum mechanics is fundamentally about the behavior of wave functions. Quite naturally, no physicist wanted this to be true more than did Erwin Schrödinger, the father of the wave function. Nonetheless, Schrödinger ultimately found this impossible to believe. His difficulty was not so much with the novelty of the wave function (Schrödinger 1935): "That it is an abstract, unintuitive mathematical construct is a scruple that almost always surfaces against new aids to thought and that carries no great message." Rather, it was that the "blurring" suggested by the spread out character of the wave function "affects macroscopically tangible and visible things, for which the term ‘blurring’ seems simply wrong."

For example, in the same paper Schrödinger noted that it may happen in radioactive decay that

> the emerging particle is described ... as a spherical wave ... that impinges continuously on a surrounding luminescent screen over its full expanse. The screen however does not show a more or less constant uniform surface glow, but rather lights up at *one* instant at *one* spot ....

And he observed that one can easily arrange, for example by including a cat in the system, "quite ridiculous cases" with

> the ψ-function of the entire system having in it the living and the dead cat (pardon the expression) mixed or smeared out in equal parts.

It is thus because of the "measurement problem," of macroscopic superpositions, that Schrödinger found it difficult to regard the wave function as "representing reality." But then what does? With evident disapproval, Schrödinger describes how

> the reigning doctrine rescues itself or us by having recourse to epistemology. We are told that no distinction is to be made between the state of a natural object and what I know about it, or perhaps better, what I can know about it if I go to some trouble. Actually -- so they say -- there is intrinsically only awareness, observation, measurement.

Many physicists pay lip service to the Copenhagen interpretation -- that quantum mechanics is fundamentally about observation or results of measurement. But it is becoming increasingly difficult to find any who, when pressed, will defend this interpretation. It seems clear that quantum mechanics is fundamentally about atoms and electrons, quarks and strings, not those particular macroscopic regularities associated with what we call *measurements* of the properties of these things. But if these entities are not to be somehow identified with the wave function itself -- and if talk of them is not merely shorthand for elaborate statements about measurements -- then where are they to be found in the quantum description?

There is, perhaps, a very simple reason why there has been so much difficulty discerning in the quantum description the objects we believe quantum mechanics should be describing. Perhaps the quantum mechanical description is not the whole story, a possibility most prominently associated with Albert Einstein.

In 1935 Einstein, Boris Podolsky and Nathan Rosen argued for this possibility in the famous EPR paper (Einstein et al. 1935), which they concluded with the following:

> While we have thus shown that the wave function does not provide a complete description of the physical reality, we left open the question of whether or not such a description exists. We believe, however, that such a theory is possible.

The argument given in the EPR paper for this conclusion invoked quantum correlations and an assumption of locality. (See the entry on quantum entanglement and information.)

Later, on the basis of more or less the same considerations as those of Schrödinger quoted above, Einstein again concluded that the wave function does not provide a complete description of individual systems, an idea he called "this most nearly obvious interpretation" (Einstein 1949, p. 672). In relation to a theory incorporating a more complete description, Einstein remarked that "the statistical quantum theory would ... take an approximately analogous position to the statistical mechanics within the framework of classical mechanics." It is perhaps worth noting here that Bohmian mechanics, as we shall see, exactly fits this description.

[Return to Table of Contents]

2. The Impossibility of Hidden Variables ... or the Inevitability of Nonlocality?

John von Neumann, one of the greatest mathematicians of the twentieth century, claimed to have mathematically proven that Einstein’s dream, of a deterministic completion or reinterpretation of quantum theory, was mathematically impossible. He concluded that (von Neumann 1932, p. 325 of the English translation)

> It is therefore not, as is often assumed, a question of a re-interpretation of quantum mechanics -- the present system of quantum mechanics would have to be objectively false, in order that another description of the elementary processes than the statistical one be possible.

This claim of von Neumann was almost universally accepted among physicists and philosophers of science. For example, Max Born, who formulated the statistical interpretation of the wave function, assured us that (Born 1949, p. 109)

> No concealed parameters can be introduced with the help of which the indeterministic description could be transformed into a deterministic one. Hence if a future theory should be deterministic, it cannot be a modification of the present one but must be essentially different.

Bohmian mechanics is, quite clearly, a counterexample to the claims of von Neumann, so something has to be wrong with von Neumann’s argument. In fact, according to John Bell (Mermin 1993, p. 805), von Neumann’s assumptions (about the relationships among the values of quantum observables that must be satisfied in a hidden-variables theory) are so unreasonable that the "the proof of von Neumann is not merely false but *foolish*!" Nonetheless, some physicists continue to rely on von Neumann’s proof, although in recent years it is more common to find physicists citing the Kochen-Specker Theorem and, more frequently, Bell’s inequality as the basis of this refutation. We still find, a quarter of a century after the rediscovery of Bohmian mechanics in 1952, statements such as these (Wigner 1976):

> The proof he [von Neumann] published ..., though it was made much more convincing later on by Kochen and Specker, still uses assumptions which, in my opinion, can quite reasonably be questioned. ... In my opinion, the most convincing argument against the theory of hidden variables was presented by J. S. Bell (1964).

Now there are many more statements of a similar character that could have been cited. This quotation owes its significance to the fact that Wigner was not only one of the leading physicists of his generation, but, unlike most of his contemporaries, he was also profoundly concerned with the conceptual

foundations of quantum mechanics and wrote on the subject with great clarity and insight.

There was, however, one physicist who wrote on this subject with even greater clarity and insight than Wigner himself, namely the very J. S. Bell whom Wigner praises for demonstrating the impossibility of a deterministic completion of quantum theory such as Bohmian mechanics. Here's how Bell himself reacted to Bohm's discovery (Bell 1987, p. 160):

> But in 1952 I saw the impossible done. It was in papers by David Bohm. Bohm showed explicitly how parameters could indeed be introduced, into nonrelativistic wave mechanics, with the help of which the indeterministic description could be transformed into a deterministic one. More importantly, in my opinion, the subjectivity of the orthodox version, the necessary reference to the 'observer,' could be eliminated. ...
>
> But why then had Born not told me of this 'pilot wave'? If only to point out what was wrong with it? Why did von Neumann not consider it? More extraordinarily, why did people go on producing ''impossibility'' proofs, after 1952, and as recently as 1978? ... Why is the pilot wave picture ignored in text books? Should it not be taught, not as the only way, but as an antidote to the prevailing complacency? To show us that vagueness, subjectivity, and indeterminism, are not forced on us by experimental facts, but by deliberate theoretical choice?

Wigner to the contrary notwithstanding, Bell did not establish the impossibility of a deterministic reformulation of quantum theory, nor did he ever claim to have done so. On the contrary, over the course of the past several decades, until his untimely death in 1990, Bell was the prime proponent, for a good part of this period almost the sole proponent, of the very theory, Bohmian mechanics, that he is supposed to have demolished.

Bohmian mechanics is of course as much a counterexample to the Kochen-Specker argument for the impossibility of hidden variables as it is to the one of von Neumann. It is obviously a counterexample to any such argument. However reasonable the assumptions of such an argument, some of them must fail for Bohmian mechanics.

Wigner was quite right to suggest that the assumptions of Kochen and Specker are more convincing than those of von Neumann. They appear, in fact, to be quite reasonable indeed . However, they are not. The impression that they are arises from a pervasive error, a naive realism about operators, that will be discussed below in the sections on quantum observables, on spin, and on contextuality.

One of the achievements of John Bell was to replace the "arbitrary axioms" (Bell 1987, page 11) of Kochen-Specker and others by an assumption of locality, of no action-at-a-distance. It would be hard to argue against the reasonableness of such an assumption, even if one were so bold as to doubt its inevitability. Bell showed that any hidden-variables formulation of quantum mechanics must be nonlocal, as, indeed, Bohmian mechanics is. But he showed much much more.

In a celebrated paper published in 1964, Bell showed that quantum theory itself is irreducibly nonlocal. This fact about quantum mechanics, based as it is on a short and mathematically simple analysis, could have been recognized soon after the discovery of quantum theory in the 1920's. That this did not happen is no doubt due in part to the obscurity of orthodox quantum theory and to the ambiguity of its commitments. It was, in fact, his examination of Bohmian mechanics that led Bell to his nonlocality analysis. In the course of his investigation of Bohmian mechanics he observed that (Bell 1987, p. 11):

> in this theory an explicit causal mechanism exists whereby the disposition of one piece of apparatus affects the results obtained with a distant piece.
>
> Bohm of course was well aware of these features of his scheme, and has given them much attention. However, it must be stressed that, to the present writer's knowledge, there is no *proof* that *any* hidden variable account of quantum mechanics *must* have this extraordinary character. It would therefore be interesting, perhaps, to pursue some further "impossibility proofs," replacing the arbitrary axioms objected to above by some condition of locality, or of separability of distant systems.

In a footnote, Bell added that "Since the completion of this paper such a proof has been found." This proof was published in his 1964 paper, "On the Einstein-Podolsky-Rosen Paradox," in which he derives Bell's inequality, the basis of his conclusion of quantum nonlocality. (For a discussion of how nonlocality emerges in Bohmian mechanics, see Section 13.)

It is worth stressing that Bell's analysis indeed shows that any account of quantum phenomena must be nonlocal, not just any hidden variables account. Bell showed that nonlocality is implied by the predictions of standard quantum theory itself. Thus if nature is governed by these predictions, then nature is nonlocal. [That nature is so governed, even in the crucial EPR-correlation experiments, has by now been established by a great many experiments, the most conclusive of which is perhaps that of Aspect (Aspect et al., 1982).]

Bell, too, stressed this point (by determinism Bell here means hidden variables):

> It is important to note that to the limited degree to which *determinism* plays a role in the EPR argument, it is not assumed but *inferred*. What is held sacred is the principle of 'local causality' -- or 'no action at a distance'...
>
> It is remarkably difficult to get this point across, that determinism is not a *presupposition* of the analysis. (Bell 1987, p. 143)
>
> Despite my insistence that the determinism was inferred rather than assumed, you might still suspect somehow that it is a preoccupation with determinism that creates the problem. Note well then that the following argument makes no mention whatever of determinism. ...

> Finally you might suspect that the very notion of particle, and particle orbit ... has somehow led us astray. ... So the following argument will not mention particles, nor indeed fields, nor any other particular picture of what goes on at the microscopic level. Nor will it involve any use of the words 'quantum mechanical system', which can have an unfortunate effect on the discussion. The difficulty is not created by any such picture or any such terminology. It is created by the predictions about the correlations in the visible outputs of certain conceivable experimental set-ups. (Bell 1987, p. 150)

The "problem" and "difficulty" to which Bell refers above is the conflict between the predictions of quantum theory and what can be inferred, call it C, from an assumption of locality in Bohm's version of the EPR argument, a conflict established by Bell's inequality. C happens to concern the existence of a certain kind of hidden variables, what might be called local hidden variables, but this fact is of little substantive importance. What is important is not so much the identity of C as the fact that C is incompatible with the predictions of quantum theory. The identity of C is, however, of great historical significance: It is responsible for the misconception that Bell proved that hidden variables are impossible, a belief until recently almost universally shared by physicists, as well as for the view, even now almost universally held, that what Bell's result does is to rule out local hidden variables, a view that is misleading.

Here again is Bell, expressing the logic of his *two-part* demonstration of quantum nonlocality, the first part of which is Bohm's version of the EPR argument:

> Let me summarize once again the logic that leads to the impasse. The EPRB correlations are such that the result of the experiment on one side immediately foretells that on the other, whenever the analyzers happen to be parallel. If we do not accept the intervention on one side as a causal influence on the other, we seem obliged to admit that the results on both sides are determined in advance anyway, independently of the intervention on the other side, by signals from the source and by the local magnet setting. But this has implications for non-parallel settings which conflict with those of quantum mechanics. So we *cannot* dismiss intervention on one side as a causal influence on the other. (Bell 1987, p. 149)

[Return to Table of Contents]

3. History

The pilot-wave approach to quantum theory was initiated, even before the discovery of quantum mechanics itself, by Einstein, who hoped that interference phenomena involving particle-like photons could be explained if the motion of the photons were somehow guided by the electromagnetic field -- which would thus play the role of what he called a *Führungsfeld* or guiding field (Wigner 1976, p. 262). While the notion of the electromagnetic field as guiding field turned out to be rather problematical, the possibility that for a system of electrons the wave function might play this role, of guiding field or pilot

wave, was explored by Max Born in his early paper founding quantum scattering theory (Born 1926) -- a suggestion to which Heisenberg was profoundly unsympathetic.

Not long after Schrödinger's discovery, in 1926, of wave mechanics, i.e., of Schrödinger's equation, Louis de Broglie in effect discovered Bohmian mechanics: In 1927, de Broglie found an equation of particle motion equivalent to the guiding equation for a scalar wave function (de Broglie 1928, p. 119), and he explained at the 1927 Solvay Congress how this motion could account for quantum interference phenomena. However, de Broglie responded poorly to an objection of Wolfgang Pauli (Pauli 1928) concerning inelastic scattering, no doubt making a rather bad impression on the illustrious audience gathered for the occasion.

Born and de Broglie very quickly abandoned the pilot-wave approach and became enthusiastic supporters of the rapidly developing consensus in favor of the Copenhagen interpretation. Bohmian mechanics was rediscovered in 1952 by David Bohm (Bohm 1952), the first person genuinely to understand its significance and implications. Its principal proponent during the sixties, seventies and eighties was John Bell.

[Return to Table of Contents]

4. The Defining Equations of Bohmian Mechanics

In Bohmian mechanics the wave function, obeying Schrödinger's equation, does not provide a complete description or representation of a quantum system. Rather, it governs the motion of the fundamental variables, the positions of the particles: In the Bohmian mechanical version of nonrelativistic quantum theory, quantum mechanics is fundamentally about the behavior of particles; the particles are described by their positions, and Bohmian mechanics prescribes how these change with time. In this sense, for Bohmian mechanics the particles, described by their positions, are primary, or primitive, while the wave function is secondary, or derivative.

Bohmian mechanics is the minimal completion of Schrödinger's equation, for a nonrelativistic system of particles, to a theory describing a genuine motion of particles. For Bohmian mechanics the state of a system of N particles is described by its wave function $\psi = \psi(\boldsymbol{q}_1,\dots,\boldsymbol{q}_N) = \psi(q)$, a complex (or spinor) valued function on the space of possible configurations q of the system, together with its actual configuration Q defined by the actual positions $\mathbf{Q}_1,\dots,\mathbf{Q}_N$ of its particles. The theory is then defined by two evolution equations: Schrödinger's equation

$$i\hbar(\partial\psi/\partial t) = H\psi$$

for $\psi(t)$, where H is the nonrelativistic (Schrödinger) Hamiltonian, containing the masses of the particles and a potential energy term, and a first-order evolution equation,

The Guiding Equation:
$d\mathbf{Q}_k/dt = (\hbar/m_k) \operatorname{Im} [\psi^* \partial_k \psi / \psi^* \psi] (\mathbf{Q}_1,...,\mathbf{Q}_N)$

for $Q(t)$, the simplest first-order evolution equation for the positions of the particles that is compatible with the Galilean (and time-reversal) covariance of the Schrödinger evolution (Dürr et al. 1992, pp. 852-854). Here $\hbar$ is Planck's constant divided by 2π, m_k is the mass of the k-th particle, and ∂_k is the gradient with respect to the coordinates of the k-th particle. If ψ is spinor-valued, the products in numerator and denominator should be understood as scalar products. If external magnetic fields are present, the gradient should be understood as the covariant derivative, involving the vector potential. (Since the denominator on the right hand side of the guiding equation vanishes at the nodes of ψ, global existence and uniqueness for the Bohmian dynamics is a nontrivial matter. It is proven in Berndl, Dürr, et al. 1995.)

For an N-particle system these two equations (together with the detailed specification of the Hamiltonian, including all interactions contributing to the potential energy) completely define the Bohmian mechanics. This deterministic theory of particles in motion accounts for all the phenomena of nonrelativistic quantum mechanics, from interference effects to spectral lines (Bohm 1952, pp. 175-178) to spin (Bell 1964, p. 10), and it does so in an entirely ordinary manner, as we shall explain in the following sections.

The form of the guiding equation given above is, for a scalar wave function, describing particles without spin, a little more complicated than necessary, since the complex conjugate of the wave function, appearing in the numerator and the denominator, cancels. If one looks for an evolution equation for the configuration compatible with the space-time symmetries of Schrödinger's equation, one almost immediately arrives at the guiding equation in this simpler form as the simplest possibility.

However, the form given above has two advantages: First, it makes sense for particles with spin -- and all the apparently paradoxical quantum phenomena associated with spin are, in fact, thereby accounted for by Bohmian mechanics without further ado. Secondly, and this is crucial to the fact that Bohmian mechanics is empirically equivalent to orthodox quantum theory, the right hand side of the guiding equation is J/ρ, the ratio of the quantum probability current to the quantum probability density. This shows first of all that it should require no imagination whatsoever to guess the guiding equation from Schrödinger's equation, provided one is looking for one, since the classical formula for current is density times velocity. Moreover, it follows from the quantum continuity equation $\partial\rho/\partial t + \operatorname{div} J = 0$, an immediate consequence of Schrödinger's equation, that if at some time (say the initial time) the configuration Q of our system is random, with distribution given by $|\psi|^2 = \psi^*\psi$, this will be true at all times (so long as the system does not interact with its environment).

This demonstrates that all claims to the effect that the predictions of quantum theory are incompatible with the existence of hidden variables, with an underlying deterministic model in which quantum randomness arises from averaging over ignorance, are wrong. For Bohmian mechanics provides us with

just such a model: For any quantum experiment we merely take as the relevant Bohmian system the combined system that includes the system upon which the experiment is performed as well as all the measuring instruments and other devices used in performing the experiment (together with all other systems with which these have significant interaction over the course of the experiment). The "hidden variables" model is then obtained by regarding the initial configuration of this big system as random in the usual quantum mechanical way, with distribution given by $|\psi|^2$. The initial configuration is then transformed, via the guiding equation for the big system, into the final configuration at the conclusion of the experiment. It then follows that this final configuration of the big system, including in particular the orientation of instrument pointers, will also be distributed in the quantum mechanical way, so that this deterministic Bohmian model yields the usual quantum predictions for the results of the experiment.

As the preceding paragraph suggests, and as we discuss in more detail in later sections, in Bohmian mechanics there is no need -- and, indeed, no room -- for any "measurement postulates" or *axioms* governing the behavior of other "observables": Any such axioms would be at best redundant, and would quite possibly be inconsistent.

5. The Quantum Potential

Bohmian mechanics has been presented here as a first-order theory, in which it is the velocity, the rate of change of position, that is fundamental: it is this quantity, given by the guiding equation, that is specified by the theory, directly and simply, with the second-order (Newtonian) concepts of acceleration and force, work and energy playing no fundamental role. Bohm, however, did not regard his theory in this way. He regarded it, fundamentally, as a second-order theory, describing particles moving under the influence of forces, among which, however, one must include a force stemming from a "quantum potential."

In his 1952 hidden-variables paper (Bohm 1952), Bohm arrived at his theory by writing the wave function in the polar form $\psi = R\exp(iS/\hbar)$, where S and R are real, with R nonnegative, and rewriting Schrödinger’s equation in terms of these new variables to obtain a pair of coupled evolution equations: the continuity equation for $\rho = R^2$ and a modified Hamilton-Jacobi equation for S, differing from the usual classical Hamilton-Jacobi equation only by the appearance of an extra term, the *quantum potential*

$$U = -\Sigma_k(\hbar^2/2m_k)\,(\partial_k^2 R / R),$$

alongside the classical potential energy term.

Bohm then used the modified Hamilton-Jacobi equation to define particle trajectories just as is done for the classical Hamilton-Jacobi equation, that is, by identifying $\partial_k S$ with $m_k \mathbf{v}_k$, i.e., by setting

$$d\mathbf{Q}_k/dt = \partial_k S \,/\, m_k,$$

which is equivalent to the guiding equation for particles without spin. [Notice that in this form the guiding equation is already suggested by the (pre-Schrödinger equation) de Broglie relation $\boldsymbol{p} = \hbar \boldsymbol{k}$, as well as by the eikonal equation of classical optics.] The resulting motion is precisely what would be obtained classically if the particles were acted upon by, in addition to the usual forces, the force generated by the quantum potential.

The quantum potential formulation of the de Broglie-Bohm theory is still fairly widely used. For example, the theory is presented in this way in the two existing monographs, by Bohm and Hiley and by Holland. And regardless of whether or not we regard the quantum potential as fundamental, it can in fact be quite useful. In order most simply to see that Newtonian mechanics should be expected to emerge from Bohmian mechanics in the classical limit, it is convenient to transform the theory into Bohm's Hamilton-Jacobi form. One then sees that the (size of the) quantum potential provides a measure of the deviation of Bohmian mechanics from its classical approximation. Moreover, the quantum potential can also be used to develop approximation schemes for solutions to Schrödinger's equation (Nerukh and Frederick 2000).

However, Bohm's rewriting of Schrödinger's equation in terms of variables that seem interpretable in classical terms does not come without a cost. The most obvious is increased complexity: Schrödinger's equation is rather simple, not to mention linear, whereas the modified Hamilton-Jacobi equation is somewhat complicated, and highly nonlinear -- and still requires the continuity equation for its closure. The quantum potential itself is neither simple nor natural. Even to Bohm it has seemed "rather strange and arbitrary" (Bohm 1980, p. 80). And it is not very satisfying to think of the quantum revolution as amounting to the insight that nature is classical after all, except that there is in nature what appears to be a rather ad hoc additional force term, the one arising from the quantum potential. The artificiality suggested by the quantum potential is the price one pays if one insists on casting a highly nonclassical theory into a classical mold.

Moreover, the connection between classical mechanics and Bohmian mechanics that is suggested by the quantum potential is rather misleading. Bohmian mechanics is not simply classical mechanics with an additional force term. In Bohmian mechanics the velocities are not independent of positions, as they are classically, but are constrained by the guiding equation. In classical Hamilton-Jacobi theory we also have this equation for the velocity, but there the Hamilton-Jacobi function S can be entirely eliminated and the description in terms of S simplified and reduced to a finite-dimensional description, with basic variables the positions and the (unconstrained) momenta of all the particles, given by Hamilton's or Newton's equations.

It can be argued that the most serious flaw in the quantum potential formulation of Bohmian mechanics is that it gives a completely false impression of the lengths to which we must go in order to convert orthodox quantum theory into something more rational. The quantum potential suggests, and indeed it has often been stated, that in order to transform Schrödinger's equation into a theory that can, in what are

often called "realistic" terms, account for quantum phenomena, many of which are dramatically nonlocal, we must add to the theory a complicated quantum potential of a grossly nonlocal character. It should be clear that such sentiments are inappropriate, since the quantum potential need not be mentioned in the *formulation* of Bohmian mechanics and in any case is merely a reflection of the wave function, which Bohmian mechanics does not add to but shares with orthodox quantum theory.

6. The Two-Slit Experiment

According to Richard Feynman, the two-slit experiment for electrons is (Feynman et al. 1963, p. 37-2) "a phenomenon which is impossible, *absolutely* impossible, to explain in any classical way, and which has in it the heart of quantum mechanics. In reality it contains the *only* mystery." This experiment (Feynman 1967, p. 130) "has been designed to contain all of the mystery of quantum mechanics, to put you up against the paradoxes and mysteries and peculiarities of nature one hundred per cent." As to the question (Feynman 1967, p. 145), "How does it really work? What machinery is actually producing this thing? Nobody knows any machinery. Nobody can give you a deeper explanation of this phenomenon than I have given; that is, a description of it."

But Bohmian mechanics is just such a deeper explanation. It resolves the dilemma of the appearance, in one and the same phenomenon, of both particle and wave properties in a rather straightforward manner: Bohmian mechanics is a theory of motion describing a particle (or particles) guided by a wave. Here we have a family of Bohmian trajectories for the two-slit experiment.

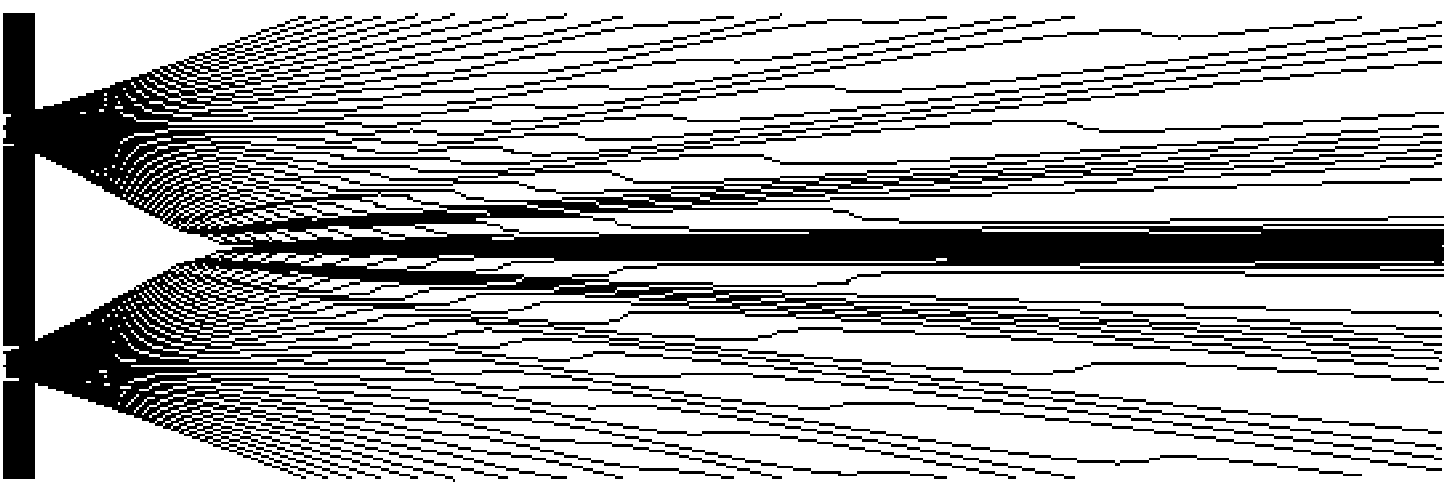

Figure 1: An ensemble of trajectories for the two-slit experiment, uniform in the slits. (Adapted by Gernot Bauer from Philippidis et al. 1979.)

While each trajectory passes through but one of the slits, the wave passes through both; the interference profile that therefore develops in the wave generates a similar pattern in the trajectories guided by this wave.

Compare Feynman's presentation with Bell's (Bell 1987, p. 191):

> Is it not clear from the smallness of the scintillation on the screen that we have to do with a particle? And is it not clear, from the diffraction and interference patterns, that the motion of the particle is directed by a wave? De Broglie showed in detail how the motion of a particle, passing through just one of two holes in screen, could be influenced by waves propagating through both holes. And so influenced that the particle does not go where the waves cancel out, but is attracted to where they cooperate. This idea seems to me so natural and simple, to resolve the wave-particle dilemma in such a clear and ordinary way, that it is a great mystery to me that it was so generally ignored.

The most puzzling aspect of the two-slit experiment is perhaps the following: If, by any means whatsoever, one is able to determine through which slit the particle passes, the interference pattern will be destroyed. This dramatic effect of observation is, in fact, a simple consequence of Bohmian mechanics. To see this one need only carefully consider what determining the slit through which the particle passes should mean. In particular, one must recognize that this must involve interaction with another system that must also be included in the Bohmian mechanical analysis. This destruction of interference is related, naturally enough, to the Bohmian mechanical analysis of quantum measurement (Bohm 1952), and it occurs via the mechanism that leads, in Bohmian mechanics, to the "collapse of the wave function."

7. The Measurement Problem

The most commonly cited of the conceptual difficulties that plague quantum mechanics is the measurement problem, or, what amounts to more or less the same thing, the paradox of Schrödinger's cat. Indeed, for many physicists the measurement problem is not merely one of the conceptual difficulties of quantum mechanics; it is *the* conceptual difficulty.

The problem is as follows. Suppose that the wave function of any individual system provides a complete description of that system. When we analyze the process of measurement in quantum mechanical terms, we find that the after-measurement wave function for system and apparatus arising from Schrödinger's equation for the composite system typically involves a superposition over terms corresponding to what we would like to regard as the various possible results of the measurement -- e.g., different pointer orientations. It is difficult to discern in this description of the after-measurement situation the actual result of the measurement -- e.g., some specific pointer orientation. But the whole point of quantum theory, and the reason we are to believe in it, is that it is supposed to provide a compelling, or at least an efficient, account of our observations, that is, of outcomes of measurements. In short, the measurement problem is this: Quantum theory implies that measurements typically fail to have outcomes of the sort the theory was created to explain.

By contrast, if, like Einstein, we regard the description provided by the wave function as incomplete, the measurement problem vanishes: With a theory or interpretation like Bohmian mechanics, in which the description of the after-measurement situation includes, in addition to the wave function, at least the values of the variables that register the result, there is no measurement problem. In Bohmian mechanics pointers always point.

The measurement problem is often expressed a little differently. It is noted that textbook quantum theory provides two rules for the evolution of the wave function of a quantum system: A deterministic dynamics given by Schrödinger’s equation for when the system is not being "measured" or observed, and a random collapse of the wave function to an *eigenstate* of the "measured observable" for when it is. However, the objection continues, textbook quantum theory does not provide a coherent account of how these two apparently incompatible rules can be reconciled.

That this formulation of the measurement problem is more or less equivalent to the previous one should be reasonably clear: If a wave function provides a complete description of the after-measurement situation, the outcome of the measurement must correspond to a wave function describing the actual result, that is, a "collapsed" wave function. Hence the collapse rule. But it is difficult to take seriously the idea that those interactions between system and apparatus that we happen to call measurements should be governed by laws different from those governing all other interactions. Hence the apparently incompatibility of the two rules.

The second formulation of the measurement problem, though basically equivalent to the first one, suggests an important question: Can Bohmian mechanics itself provide a coherent account of how the two dynamical rules might be reconciled? How does Bohmian mechanics justify the use of the "collapsed" wave function in place of the original one? This question was answered in Bohm’s first papers on Bohmian mechanics (Bohm 1952, Part I, Section 7, and Part II, Section 2). What would nowadays be called effects of decoherence, produced by interaction with the environment (air molecules, cosmic rays, internal microscopic degrees of freedom, etc.), make it extremely difficult for the component of the after-measurement wave function corresponding to the actual result of the measurement to develop significant overlap -- in the configuration space of the very large system that includes all systems with which the original system and apparatus come into interaction -- with the other components of the after-measurement wave function. But without such overlap the future evolution of the configuration of the system and apparatus is generated, to a high degree of accuracy, by that component all by itself. The replacement is thus justified as a practical matter. (See also Dürr et al. 1992, Section 5.)

It is widely believed by proponents of orthodox quantum theory that the measurement problem itself is somehow resolved by decoherence. It is not easy to understand this belief. In the first formulation of the measurement problem, nothing prevents us from including in the apparatus all sources of decoherence. But then there is no longer any room for decoherence to be in any way relevant to that argument. Be that as it may, one of the best descriptions of the mechanisms of decoherence, though not the word itself, was given by Bohm (Bohm 1952), who recognized its importance several decades before it became

fashionable. (See also the encyclopedia entry on The Role of Decoherence in Quantum Mechanics.)

[Return to Table of Contents]

8. The Collapse of the Wave Function

In the previous section it was indicated that collapse of the wave function can be regarded in Bohmian mechanics as a pragmatic affair. However, there is a sense in which the collapse of the wave function in Bohmian mechanics is more than a matter of convenience. If we focus on what should be regarded as the wave function, not of the composite of system and apparatus -- which strictly speaking remains a superposition if the composite is treated as closed during the measurement process -- but of the system itself, we find that for Bohmian mechanics this does indeed collapse, precisely as described by the quantum formalism. The key element here is the notion of the *conditional wave function* of a subsystem of a larger system, described briefly in this section and discussed in some detail, together with the related notion of the effective wave function, in Dürr et al. 1992, Section 5.

For the evolution of the wave function, Bohmian mechanics is formulated in terms of Schrödinger's equation alone. Nonetheless the textbook collapse rule is a consequence of the Bohmian dynamics. To appreciate this one should first note that, since observation implies interaction, a system under observation cannot be a closed system but rather must be a subsystem of a larger system that is closed, which we may take to be the entire universe, or any smaller more or less closed system that contains the system to be observed, *the subsystem*. The configuration Q of this larger system naturally splits into X, the configuration of the subsystem, and Y, the configuration of the *environment* of the subsystem.

Suppose the larger system has wave function $\Psi = \Psi(q) = \Psi(x, y)$. According to Bohmian mechanics, the larger system is then completely described by Ψ, evolving according to Schrödinger's equation, together with X and Y. The question then arises -- and it is a critical question -- as to what should be meant by the wave function of the subsystem.

There is a rather obvious answer for this, a natural function of x that suitably incorporates the objective structure at hand, namely the *conditional wave function*

$$\psi(x) = \Psi(x, Y)$$

obtained by plugging the actual configuration of the environment into the wave function of the larger system. (This definition is appropriate only for scalar wave functions; for particles with spin the situation would be a little more complicated.) It then follows immediately that the configuration of the subsystem obeys the guiding equation with the conditional wave function on its right hand side.

Moreover, taking into account the way that the conditional wave function depends upon time t

$$\psi_t(x) = \Psi_t(x, Y_t)$$

via the time dependence of Y as well as that of Ψ, it is not difficult to see (Dürr et al. 1992) that the conditional wave function obeys Schrödinger's equation for the subsystem when that system is suitably decoupled from its environment -- this is meant to imply, in particular, that Ψ has a special form, what might be called an effective product form (similar to but more general than the superposition produced in an "ideal quantum measurement"), in which case the conditional wave function of the subsystem is also called its *effective wave function* -- and, using the quantum equilibrium hypothesis, that it randomly collapses according to the usual quantum mechanical rules under precisely those conditions on the interaction between the subsystem and its environment that define an ideal quantum measurement.

It is perhaps worth noting that orthodox quantum theory lacks the resources, namely, the actual configuration of the environment, that make possible the definition of the conditional wave function. Indeed, from an orthodox point of view what should be meant by the wave function of a subsystem is entirely obscure.

[Return to Table of Contents]

9. Quantum Randomness

According to the quantum formalism, the probability density for finding a system whose wave function is ψ in the configuration q is $|\psi(q)|^2$. To the extent that the results of measurement are registered configurationally, at least potentially, it follows that the predictions of Bohmian mechanics for the results of measurement must agree with those of orthodox quantum theory (assuming the same Schrödinger equation for both) provided that it is somehow true for Bohmian mechanics that configurations are random, with distribution given by the *quantum equilibrium* distribution $|\psi(q)|^2$. Now the status and justification of this *quantum equilibrium hypothesis* is a rather delicate matter, one that has been explored in considerable detail (Dürr et al. 1992). Here are but a few relevant points.

It is nowadays a rather familiar fact that dynamical systems quite generally give rise to behavior of a statistical character, with the statistics given by the (or a) stationary probability distribution for the dynamics. So it is with Bohmian mechanics, except that for the Bohmian system stationarity is not quite the right concept, and it is rather the notion of *equivariance* that is relevant. A probability distribution ρ^ψ on configuration space, depending upon the wave function ψ, is *equivariant* if

$$(\rho^\psi)_t = \rho^{\psi_t}$$

where the dependence on t on the right arises from Schrödinger's equation and on the left from the evolution on probability distributions arising from the flow induced by the guiding equation. Thus

equivariance expresses the mutual compatibility, relative to ρ^{ψ}, of the Schrödinger evolution of the wave function and the Bohmian motion of the configuration. It is an immediate consequence of the guiding equation and the quantum continuity equation that $\rho^{\psi} = |\psi(q)|^2$ is equivariant.

It is perhaps helpful, in trying to understand the status in Bohmian mechanics of the quantum equilibrium distribution, to think of

quantum equilibrium, $\rho = |\psi|^2$

as roughly analogous to (classical)

thermodynamic equilibrium, $\rho = \exp(-H/kT)/Z$,

the probability distribution of the phase-space point of a system in equilibrium at temperature *T*. (*Z* is a normalization constant called the partition function and *k* is Boltzmann's constant.) This analogy has several facets: In both cases the probability distributions are naturally associated with their respective dynamical systems. In particular, these distributions are stationary or, what amounts to the same thing within the framework of Bohmian mechanics, equivariant. In both cases it appears natural to try to justify these equilibrium distributions by means of mixing-type, convergence-to-equilibrium arguments (Bohm 1953, Valentini 2001). In both cases the ultimate justification for these probability distributions must, arguably, be in terms of statistical patterns exhibited by ensembles of actual subsystems within a *typical* individual universe (Bell 1987, page 129, Dürr et al. 1992). (And in both cases the status of, and justification for, equilibrium distributions is still controversial.) It can be shown (Dürr et al. 1992) that probabilities for positions given by the quantum equilibrium distribution emerge naturally from an analysis of "equilibrium" for the deterministic dynamical system defined by Bohmian mechanics, in much the same way that the Maxwellian velocity distribution emerges from an analysis of classical thermodynamic equilibrium. (For more on the thermodynamic side of the analogy see Goldstein 2001.) Thus with Bohmian mechanics the statistical description in quantum theory indeed takes, as Einstein anticipated, "an approximately analogous position to the statistical mechanics within the framework of classical mechanics."

[Return to Table of Contents]

10. Quantum Observables

It would appear that because orthodox quantum theory supplies us with probabilities not merely for positions but for a huge class of quantum observables, it is a much richer theory than Bohmian mechanics, which seems exclusively concerned with positions. Appearances are, however, misleading. In this regard, as with so much else in the foundations of quantum mechanics, the crucial remark has been made by Bell (Bell 1987, p. 166):

> [I]n physics the only observations we must consider are position observations, if only the positions of instrument pointers. It is a great merit of the de Broglie-Bohm picture to force us to consider this fact. If you make axioms, rather than definitions and theorems, about the "measurement" of anything else, then you commit redundancy and risk inconsistency.

Consider first classical mechanics. The observables are functions on phase space, functions of the positions and momenta of the particles. The theory is defined by the axioms governing the behavior of the basic observables -- Newton's equations for the positions or Hamilton's for positions and momenta. What would be the point of making additional axioms, for other observables? After all, the behavior of any observable is entirely determined by the behavior of the basic observables. For example, for classical mechanics, the principle of the conservation of energy is a theorem, not an axiom.

The situation might seem to be different in quantum mechanics, since in quantum mechanics there are no basic observables having the property that all other observables are functions of these. This is connected with the fact that in quantum mechanics, with its positivistic orientation, no observables are taken seriously as describing objective properties, as actually having values regardless of whether they are or have been measured. Rather, all talk of observables in quantum mechanics is supposed to be understood as talk about the measurement of the observables.

But if this is so, the situation with regard to other observables in quantum mechanics is not really that different from in classical mechanics. Whatever is supposed to be meant in quantum mechanics by the measurement of (the values of) observables -- that, we are urged to believe, don't actually have values -- it must at least refer to some experiment involving interaction between the "measured" system and a "measuring" apparatus leading to a recognizable result, as given potentially by, say, a pointer orientation. But then if the axioms that we do have suffice for the behavior of pointer orientations (at least when they are observed), rules about the measurement of other observables must be theorems, following from those axioms, not additional axioms.

It should be clear from the discussion towards the end of Section 4 and at the beginning of Section 9 that, assuming the quantum equilibrium hypothesis, any analysis of the measurement of a quantum observable for orthodox quantum theory -- whatever that may be taken to mean and however the corresponding experiment may be performed -- provides ipso facto at least as adequate an account for Bohmian mechanics. The only part of orthodox quantum theory relevant to the analysis is the Schrödinger evolution, and this it *shares* with Bohmian mechanics. The main difference in the two accounts is that the orthodox one encounters the measurement problem before reaching a satisfactory conclusion while the Bohmian account does not. This difference stems of course from what Bohmian mechanics *adds* to orthodox quantum theory: actual configurations.

In the rest of this section, I wish to touch upon the significance of quantum observables for Bohmian mechanics: on how they naturally emerge and what talk of them means. (It follows from what has been said in the three preceding paragraphs that what we conclude here about quantum observables for Bohmian mechanics holds for orthodox quantum theory as well.)

It happens that Bohmian mechanics leads to a natural association between experiments and so-called *generalized observables*, given by positive-operator-valued measures (Davies 1976), or POVM's, $O(dz)$, on the value spaces for the results of the experiments (Berndl, Daumer, et al. 1995). This association is such that the probability distribution of the result Z of an experiment, when performed upon a system with wave function ψ, is given by $<\psi \mid O(dz)\psi>$ (where < | > is the usual inner product between quantum state vectors).

Moreover, this conclusion is basically an immediate consequence of the very meaning of an experiment from a Bohmian perspective: a coupling of system to apparatus leading to a result Z that is a function of the final configuration of the total system, e.g., the orientation of a pointer. Analyzed in Bohmian mechanical terms, the experiment defines a map from the initial wave function of the system to the distribution of the result. It follows directly from the structure of Bohmian mechanics, and from the fact that the quantum equilibrium distribution is quadratic in the wave function, that this map is bilinear (or, more precisely, sesquilinear). Such a map is equivalent to a POVM.

The simplest example of a POVM is a standard quantum observable, corresponding to a self-adjoint operator A on the Hilbert space of quantum states (i.e., wave functions). For Bohmian mechanics, more or less every "measurement-like" experiment is associated with this special kind of POVM, and the familiar quantum measurement axiom that the distribution of the result of the "measurement of the observable A" is given by the *spectral measure* for A relative to the wave function (in the very simplest cases just the absolute squares of the so-called *probability amplitudes*) is thus obtained.

For a variety of reasons, it quickly became almost universal, after quantum mechanics was discovered, to speak of an experiment associated with an operator A in the manner just sketched as a *measurement* of the *observable A*, as if the operator somehow corresponded to a property of the system that is in some sense measured by that experiment. There is no greater source of confusion about the meaning and implications of quantum theory than this *naive realism about operators* (Daumer et al., 1997).

[Return to Table of Contents]

11. Spin

Both the way non-configurational quantum observables are treated in Bohmian mechanics, and some of the difficulties caused by the naive realism about operators mentioned above, can be illustrated nicely with the case of spin.

Spin is the canonical quantum observable having no classical counterpart, reputed to be impossible to grasp in a nonquantum way. The source of the difficulty is not so much that spin is quantized in the sense that its allowable values form a discrete set (for a spin-1/2 particle, $\pm\hbar/2$) -- energy too may be quantized in this sense -- nor even precisely that the components of spin in the different directions fail to commute

and so cannot be simultaneously discussed, measured, imagined, or whatever it is that we are admonished not to do with noncommuting observables. Rather the difficulty is that there is no ordinary (nonquantum) quantity which, like the spin observable, is a 3-vector and which also is such that its components in all possible directions belong to the same discrete set. The problem, in other words, is that the usual vector relationships among the various components of the spin vector are incompatible with the quantization conditions on the values of these components.

For a particle of spin-1 the problem is even more severe. Since the components of spin in different directions aren't simultaneously measurable, the impossible vector relationships for the spin components of a quantum particle are not observable relationships. Simon Kochen and Ernst Specker (Kochen and Specker 1967) showed that for a spin-1 particle the squares of the spin components in the various directions satisfy, according to quantum theory, a collection of relationships, each individually observable, that taken together are impossible: the relationships are incompatible with the idea that measurements of these observables merely reveal their preexisting values rather than, as we are urged to believe in quantum theory, creating them. This Kochen-Specker Theorem continues to be regarded by many physicists and philosophers of physics as a definitive argument against the possibility of hidden variables.

We thus might naturally wonder how Bohmian mechanics manages to cope with spin. But this question has already been answered here. Bohmian mechanics makes sense for particles with spin, i.e., for particles whose wave functions are spinor-valued. When such particles are suitably directed toward Stern-Gerlach magnets, they emerge moving in more or less a discrete set of directions -- 2 possible directions for a spin-1/2 particle, having 2 spin components, 3 for spin-1 with 3 spin components, and so on. This occurs because the Stern-Gerlach magnets are so designed and so oriented that a wave packet (a localized wave function with reasonably well defined velocity) directed towards the magnet will, by virtue of the Schrödinger evolution, separate into distinct packets -- corresponding to the spin components of the wave function and moving in the discrete set of directions. The particle itself, depending upon its initial position, ends up in one of the packets moving in one of the directions.

The probability distribution for the result of such a *Stern-Gerlach experiment* is conveniently expressed in terms of the quantum mechanical spin operators -- for a spin-1/2 particle given by the Pauli spin matrices -- in the manner alluded to above. From a Bohmian perspective there is no hint of paradox in any of this unless we are seduced by naive realism about operators into insisting, despite its evident impossibility, that the spin operators correspond to genuine properties of the particles.

[Return to Table of Contents]

12. Contextuality

The Kochen-Specker Theorem, the earlier theorem of Gleason (Gleason 1957 and Bell 1966), as well as a variety of other no-hidden-variables results, including Bell's inequality (Bell 1964), show that any hidden-

variables formulation of quantum mechanics must be *contextual*. It must violate the noncontextuality assumption "that measurement of an observable must yield the same value independently of what other measurements may be made simultaneously" (Bell 1987, p. 9). To many physicists and philosophers of science contextuality has seemed too great a price to pay for the rather modest benefits -- largely psychological, so they would say -- provided by hidden variables.

Even many Bohmians suggest that contextuality marks a significant departure from classical principles. For example, Bohm and Hiley (1993) write that "The context dependence of results of measurements is a further indication of how our interpretation does not imply a simple return to the basic principles of classical physics."

However, to understand contextuality from the perspective of Bohmian mechanics is to appreciate that almost nothing needs to be explained. Consider an operator *A* that commutes with operators *B* and *C* (which however don't commute with each other). What is often called the "result for *A*" in an experiment for "measuring *A* together with *B*" usually disagrees with the "result for *A*" in an experiment for "measuring *A* together with *C*" because, even if everything else is the same, these experiments are different and different experiments usually have different results. The misleading reference to measurement, with the associated naive realism about operators, makes contextuality seem more than it is.

If we avoid naive realism about operators, contextuality amounts to little more than the rather unremarkable observation that results of experiments should depend upon how they are performed, even when the experiments considered are associated with the same operator in the manner alluded to above. David Albert (Albert 1992, p. 153) has given a particularly simple and striking example of this dependence for Stern-Gerlach experiments "measuring" the *z*-component of spin. If one reverses the polarity in a magnet for "measuring" the *z*-component of spin, keeping the same geometry, one obtains another magnet for "measuring" the *z*-component of spin. The use of one or the other of these two magnets will often lead to opposite conclusions about the "value of the *z*-component of spin" prior to the "measurement" (for the same initial value of the position of the particle).

As Bell has insisted (Bell 1987, p. 166):

> A final moral concerns terminology. Why did such serious people take so seriously axioms which now seem so arbitrary? I suspect that they were misled by the pernicious misuse of the word 'measurement' in contemporary theory. This word very strongly suggests the ascertaining of some preexisting property of some thing, any instrument involved playing a purely passive role. Quantum experiments are just not like that, as we learned especially from Bohr. The results have to be regarded as the joint product of 'system' and 'apparatus,' the complete experimental set-up. But the misuse of the word 'measurement' makes it easy to forget this and then to expect that the 'results of measurements' should obey some simple logic in which the apparatus is not mentioned. The resulting difficulties soon show that any such logic is not ordinary logic. It is my impression that the whole vast subject of

> ‘Quantum Logic’ has arisen in this way from the misuse of a word. I am convinced that the word ‘measurement’ has now been so abused that the field would be significantly advanced by banning its use altogether, in favour for example of the word ‘experiment.’

13. Nonlocality

Bohmian mechanics is manifestly nonlocal: The velocity, as expressed in the guiding equation, of any one of the particles of a many-particle system will typically depend upon the positions of the other, possibly distant, particles whenever the wave function of the system is entangled, i.e., not a product of single-particle wave functions. This is true, for example, for the EPR-Bohm wave function, describing a pair of spin-1/2 particles in the singlet state, analyzed by Bell and many others. Thus does Bohmian mechanics make explicit the most dramatic feature of quantum theory: quantum nonlocality.

It should be emphasized that the nonlocality of Bohmian mechanics derives solely from the nonlocality built into the structure of standard quantum theory, as provided by a wave function on configuration space, an abstraction which, roughly speaking, combines -- or binds -- distant particles into a single irreducible reality. As Bell (Bell 1987, p. 115) has stressed,

> That the guiding wave, in the general case, propagates not in ordinary three-space but in a multidimensional-configuration space is the origin of the notorious ‘nonlocality’ of quantum mechanics. It is a merit of the de Broglie-Bohm version to bring this out so explicitly that it cannot be ignored.

Thus the nonlocal velocity relation in the guiding equation is but one aspect of the nonlocality of Bohmian mechanics. There is also the nonlocality, or nonseparability, implicit in the wave function itself and in its propagation, a nonlocality that does not in fact assume the structure -- actual configurations -- that Bohmian mechanics adds to orthodox quantum theory. And as Bell has shown, using the connection between the wave function and the predictions of quantum theory concerning experimental results, this nonlocality cannot easily be argued away (see Section 2).

The nonlocality of Bohmian mechanics can be appreciated perhaps most efficiently, in all its aspects, by focusing on the conditional wave function. Suppose, for example, that in an EPR-Bohm experiment particle 1 passes through its Stern-Gerlach magnet before particle 2 arrives at its magnet. Then the orientation of the Stern-Gerlach magnet for particle 1 will have a significant effect upon the conditional wave function of particle 2: If the Stern-Gerlach magnet for particle 1 is so oriented as to "measure the *z*-component of spin," then after particle 1 has passed through its magnet the conditional wave function of particle 2 will be an eigenvector (or eigenstate) of the *z*-component of spin (in fact, belonging to the eigenvalue that is the negative of the one "measured" for particle 1), and the same thing is true for any other component of spin. You can dictate the *kind* of spin eigenstate produced for particle 2 by

appropriately choosing the orientation of an arbitrarily distant magnet. As to the future behavior of particle 2, in particular how it is affected by its magnet, this of course depends very much on the character of its conditional wave function and hence is very strongly influenced by the choice of orientation of the distant magnet.

This nonlocal effect upon the conditional wave function of particle 2 follows from combining the standard analysis of the evolution of the wave function in the EPR-Bohm experiment with the definition of the conditional wave function. (For simplicity, we ignore permutation symmetry.) Before any magnets have been reached the EPR-Bohm wave function is a sum of two terms, corresponding to nonvanishing values for two of the four possible joint spin components for the two particles, each term a product of an eigenstate for a component of spin in a given direction for particle 1 with the opposite eigenstate (i.e., belonging to the eigenvalue that is the negative of the eigenvalue for particle 1) for the component of spin in the same direction for particle 2. Moreover, by virtue of its symmetry under rotations, it happens that the EPR-Bohm wave function has the property that any component of spin, i.e., any direction, can be used in this decomposition. (This property is very interesting.)

Decomposing the EPR-Bohm wave function using the component of spin in the direction associated with the magnet for particle 1, the evolution of the wave function as particle 1 passes its magnet is easy to grasp: The evolution of the sum is determined (using linearity) by that of its individual terms, and the evolution of each term by that of each of its factors. The evolution of the particle-1 factor leads to a displacement along the magnetic axis in the direction determined by the (sign of the) spin component (i.e., the eigenvalue), as described in the fourth paragraph of Section 11. Once this displacement has occurred (and is large enough) the conditional wave function for particle 2 will correspond to the term in the sum selected by the actual position of particle 1. In particular, it will be an eigenstate of the component of spin "measured by" the magnet for particle 1.

The nonlocality of Bohmian mechanics has a remarkable feature: it is screened by quantum equilibrium. It is a consequence of the quantum equilibrium hypothesis that the nonlocal effects in Bohmian mechanics don't yield observable consequences that are also controllable -- we can't use them to send instantaneous messages. This follows from the fact that, given the quantum equilibrium hypothesis, the observable consequences of Bohmian mechanics are the same as those of orthodox quantum theory, for which instantaneous communication based on quantum nonlocality is impossible (see Eberhard 1978). The importance of quantum equilibrium for obscuring the nonlocality of Bohmian mechanics has been stressed by Valentini (1991).

[Return to Table of Contents]

14. Lorentz Invariance

Like nonrelativistic quantum theory, of which it is a version, Bohmian mechanics is incompatible with special relativity, a central principle of physics: it is not Lorentz invariant. Nor can Bohmian mechanics

easily be modified to become Lorentz invariant. Configurations, defined by the *simultaneous* positions of all particles, play too crucial a role in its formulation, the guiding equation defining an evolution on *configuration* space.

This difficulty with Lorentz invariance is intimately connected with the nonlocality in Bohmian mechanics. Since quantum theory itself, by virtue merely of the character of its predictions concerning EPR-Bohm correlations, is irreducibly nonlocal (see Section 2), one might expect considerable difficulty with the Lorentz invariance of orthodox quantum theory as well with Bohmian mechanics. For example, the collapse rule of textbook quantum theory blatantly violates Lorentz invariance. As a matter of fact, the intrinsic nonlocality of quantum theory presents formidable difficulties for the development of any (many-particle) Lorentz invariant formulation that avoids the vagueness of orthodox quantum theory (see Maudlin 1994).

A somewhat surprising, and I think correct, evaluation of the importance of the problem of Lorentz invariance was made by Bell in an interview with the philosopher Renée Weber, not long before he died. Referring to the paradoxes of quantum mechanics, Bell observed that "Those paradoxes are simply disposed of by the 1952 theory of Bohm, leaving as *the* question, the question of Lorentz invariance. So one of my missions in life is to get people to see that if they want to talk about the problems of quantum mechanics -- the real problems of quantum mechanics -- they must be talking about Lorentz invariance."

The most common view on the matter of Lorentz invariance and quantum nonlocality is that a detailed description of microscopic quantum processes, such as would be provided by an extension of Bohmian mechanics to the relativistic domain, must violate Lorentz invariance. In this view Lorentz invariance is an emergent symmetry obeyed by our observations -- a statistical consequence of quantum equilibrium that governs the results of quantum experiments. This is the opinion of Bohm and Hiley (1993), of Holland (1993), and of Valentini (2001).

However -- unlike nonlocality -- violation of Lorentz invariance is not inevitable. It should be possible, it seems, to construct a fully Lorentz invariant theory providing a detailed description of microscopic quantum processes. One way to do this is by means of additional Lorentz invariant dynamical structure, for example a suitable time-like 4-vector field, that permits the definition of a foliation of space-time into space-like hypersurfaces providing a Lorentz invariant notion of "evolving configuration" and along which nonlocal effects are transmitted. See Dürr et al. 1999 for a toy model. Another possibility that should not be dismissed is that a fully Lorentz invariant account of quantum nonlocality can be achieved without the invocation of additional structure, exploiting only what is already at hand, for example, light-cone structure.

Be that as it may, Lorentz invariant nonlocality would remain somewhat enigmatic. The issues are extremely subtle. For example, Bell (1987, page 155) rightly would find "disturbing ... the impossibility of 'messages' faster than light, which follows from ordinary relativistic quantum mechanics in so far as it is unambiguous and adequate for procedures *we* [emphasis added] can actually perform. The exact elucidation of concepts like 'message' and 'we', would be a formidable challenge." While quantum

equilibrium and the absolute uncertainty that it entails (Dürr et al. 1992) may be of some help here, the situation remains puzzling.

15. Objections

Anyone who has engaged in arguments with colleagues about the foundations of quantum mechanics, whatever his position, will likely agree with the following observation of Tolstoy:

> I know that most men, including those at ease with problems of the highest complexity, can seldom accept even the simplest and most obvious truth if it be such as would oblige them to admit the falsity of conclusions which they have delighted in explaining to colleagues, which they have proudly taught to others, and which they have woven, thread by thread, into the fabric of their lives.

A great many objections have been and continue to be raised against Bohmian mechanics. Here are some of them: Bohmian mechanics makes predictions about results of experiments different from those of orthodox quantum theory so it is wrong. Bohmian mechanics makes the same predictions about results of experiments as orthodox quantum theory so it is untestable and therefore meaningless. Bohmian mechanics is mathematically equivalent to orthodox quantum theory so it is not really an alternative at all. Bohmian mechanics is more complicated than orthodox quantum theory, since it involves an extra equation. (This objection is based on the surprisingly common misconception that orthodox quantum theory is defined solely by Schrödinger's equation, and does not actually need as part of its formulation any of the measurement postulates found in textbook quantum theory. It is only within a many-worlds framework that this view could begin to make sense, but I strongly doubt that it makes sense even there.) Bohmian mechanics requires the postulation of a mysterious and undetectable quantum potential. Bohmian mechanics requires the addition to quantum theory of a mysterious pilot wave. Bohmian mechanics, as von Neumann has shown, can't possibly work. Bohmian mechanics, as Kochen and Specker have shown, can't possibly work. Bohmian mechanics, as Bell has shown, can't possibly work. Bohmian mechanics is a childish regression to discredited classical modes of thought. Bohmian trajectories are crazy, since they may be curved even when no classical forces are present. Bohmian trajectories are crazy, since a Bohmian particle may be at rest in stationary quantum states. Bohmian trajectories are crazy, since a Bohmian particle may be at rest in stationary quantum states, even when these are large-energy eigenstates. Bohmian trajectories are surrealistic. Bohmian mechanics, since it is deterministic, is incompatible with quantum randomness. Bohmian mechanics is nonlocal. Bohmian mechanics is unintuitive. Bohmian mechanics is the many-worlds interpretation in disguise. (For a bit of discussion of some of these objections, see the exchange of letters on Quantum Theory Without Observers, in the February 1999 issue of *Physics Today*, particularly the last four of the eight letters. A link is provided in the Other Internet Resources section below.)

Most of these objections have little or no merit. Some arise from naive realism about operators, some from the idea that, to the extent that the concepts of classical physics apply at all, the laws of classical physics are more or less a priori, some from an inability to grasp the point of Bohmian mechanics, and some from sheer ignorance.

It is perhaps worth mentioning that despite the empirical equivalence between Bohmian mechanics and orthodox quantum theory, there are a variety of experiments and experimental issues that don't fit comfortably within the standard quantum formalism but are easily handled by Bohmian mechanics. Among these are dwell and tunneling times (Leavens 1996), escape times and escape positions (Daumer et al. 1997a), scattering theory (Dürr et al., 2000), and quantum chaos (Cushing 1994, Dürr et al., 1992a).

There is one striking feature of Bohmian mechanics that is often presented as an objection but is better regarded as an important clue about the meaning of quantum mechanics: in Bohmian mechanics the wave function acts upon the positions of the particles but, evolving as it does autonomously via Schrödinger's equation, it is not acted upon by the particles. This point is discussed in Dürr et al. 1997 and in Goldstein and Teufel 2001, where it is suggested that, from a deeper perspective than afforded by standard Bohmian mechanics or quantum theory, the wave function should be regarded as nomological, as an object for conveniently expressing the law of motion somewhat analogous to the Hamiltonian in classical mechanics, and that a time-dependent Schrödinger-type equation, from this deeper (cosmological) perspective, is merely phenomenological.

Bohmian mechanics does not account for phenomena such as pair creation and annihilation characteristic of quantum field theory. This is not an objection to Bohmian mechanics but merely a recognition that quantum field theory explains a great deal more than does nonrelativistic quantum mechanics, whether in orthodox or Bohmian form. It does, however, underline the need to find an adequate, if not compelling, Bohmian version of quantum field theory, and of gauge theories in particular, a problem that is pretty much wide open. Some rather tentative steps in this direction can be found in Bohm and Hiley 1993, Holland 1993, Bell 1987 (p. 173), and in some of the articles in Cushing et al. 1996. (For a general discussion of this issue and of the point and value of Bohmian mechanics, see the exchange of letters between Goldstein and Weinberg by following the link provided in the Other Internet Resources section below.)

Quantum Entanglement and Information

Quantum entanglement is a physical resource, like energy, associated with the peculiar nonclassical correlations that are possible between separated quantum systems. Entanglement can be measured, transformed, and purified. A pair of quantum systems in an entangled state can be used as a quantum information channel to perform computational and cryptographic tasks that are impossible for classical systems. The general study of the information-processing capabilities of quantum systems is the subject of quantum information.

Quantum Entanglement

In 1935 and 1936, Schrödinger published a two-part article in the *Proceedings of the Cambridge Philosophical Society* in which he discussed and extended a remarkable argument by Einstein, Podolsky, and Rosen. The Einstein-Podolsky-Rosen (EPR) argument was, in many ways, the culmination of Einstein's critique of the orthodox Copenhagen interpretation of quantum mechanics, and was designed to show that the theory is incomplete. In classical mechanics the state of a system is essentially a list of the system's properties -- or, more precisely, it is the specification of a set of parameters from which the list of properties can be reconstructed: the positions and momenta of all the particles comprising the system. The dynamics of the theory specifies how properties change in terms of a law of evolution for the state. Pauli characterized this mode of description of physical systems as a ‘detached observer’ idealization (see Pauli's letter to Born in *The Born-Einstein Letters*, p. 218). On the Copenhagen interpretation, such a description is not possible for quantum systems. Instead, the quantum state of a

system should be understood as a catalogue of what an observer has done to the system and what has been observed, and the import of the state then lies in the probabilities that can be inferred (in terms of the theory) for the outcomes of possible future observations on the system. Einstein rejected this view and proposed a series of arguments to show that the quantum state is simply an incomplete characterization of the system. The missing parameters are sometimes referred to as ‘hidden parameters’ or ‘hidden variables’ (although Einstein did not use this terminology, presumably because he did not want to endorse any particular ‘hidden variable’ theory).

It should not be supposed that Einstein's definition of a complete theory included the requirement that it be deterministic. Rather, he required certain conditions of separability and locality for composite systems consisting of separated component systems: each component system separately should be characterized by its own properties (even if these properties manifest themselves stochastically), and it should be impossible to alter the properties of a distant system instantaneously (or the probabilities of these properties) by acting on a local system. In later analyses -- notably in Bell's extension of the EPR argument -- it became apparent that these conditions, suitably formulated as probability constraints, are equivalent to the requirement that statistical correlations between separated systems should be reducible to a common cause in the sense of Reichenbach.

In the original EPR article, two particles are prepared from a source in a certain quantum state and then move apart. There are ‘matching’ correlations between both the positions of the two particles and their momenta: a measurement of either position or momentum on a particular particle will allow the prediction, with certainty, of the outcome of a position measurement or momentum measurement, respectively, on the other particle. These measurements are mutually exclusive: either a position measurement can be performed, or a momentum measurement, but not both simultaneously. Either correlation can be observed, but the subsequent measurement of momentum, say, after establishing the position correlation, will no longer yield any correlation in the momenta of the two particles. It is as if the position measurement disturbs the correlation between the momentum values. The puzzle is that the quantum state of the particle pair is inconsistent with *any* assignment of precise position and momentum values to the particles separately. These values would be the common cause of the correlations, and would provide an explanation of the correlations in terms of the initial correlations between the properties of the two systems at the source. EPR concluded that the quantum state was incomplete.

Here is how Schrödinger put the puzzle in the first part of his two-part article (Schrödinger, p. 559):

> Yet since I can predict *either* x_1 or p_1 without interfering with the system No. 1 and since system No. 1, like a scholar in an examination, cannot possibly know which of the two questions I am going to ask first: it so seems that our scholar is prepared to give the right answer to the *first* question he is asked, *anyhow*. Therefore he must know both answers; which is an amazing knowledge; quite irrespective of the fact that after having given his first answer our scholar is invariably so disconcerted or tired out, that all the following answers are ‘wrong.’

What Schrödinger showed was that if two particles are prepared in a quantum state such that there is a matching correlation between two ‘canonically conjugate’ dynamical quantities -- quantities like position and momentum whose values suffice to specify all the properties of a classical system -- then there are infinitely many dynamical quantities of the two particles for which there exist similar matching correlations: every function of the canonically conjugate pair of the first particle matches with the same function of the canonically conjugate pair of the second particle. Thus (p. 559) system No. 1 ‘does not only know these two answers but a vast number of others, and that with no mnemotechnical help whatsoever, at least with none that we know of.’

Schrödinger coined the term ‘entanglement’ to describe this peculiar connection between quantum systems (Schrödinger, p. 555):

> When two systems, of which we know the states by their respective representatives, enter into temporary physical interaction due to known forces between them, and when after a time of mutual influence the systems separate again, then they can no longer be described in the same way as before, viz. by endowing each of them with a representative of its own. I would not call that *one* but rather *the* characteristic trait of quantum mechanics, the one that enforces its entire departure from classical lines of thought. By the interaction the two representatives [the quantum states] have become entangled.

He added (Schrödinger, p. 555):

> Another way of expressing the peculiar situation is: the best possible knowledge of a *whole* does not necessarily include the best possible knowledge of all its *parts*, even though they may be entirely separate and therefore virtually capable of being ‘best possibly known,’ i.e., of possessing, each of them, a representative of its own. The lack of knowledge is by no means due to the interaction being insufficiently known -- at least not in the way that it could possibly be known more completely -- it is due to the interaction itself.
>
> Attention has recently been called to the obvious but very disconcerting fact that even though we restrict the disentangling measurements to *one* system, the representative obtained for the *other* system is by no means independent of the particular choice of observations which we select for that purpose and which by the way are *entirely* arbitrary. It is rather discomforting that the theory should allow a system to be steered or piloted into one or the other type of state at the experimenter's mercy in spite of his having no access to it.

In the second part of the paper, Schrödinger showed that, in general, a sophisticated experimenter can, by a suitable choice of operations carried out on one system, steer the second system into any ‘mixture’ of quantum states he chooses, i.e., not steer the system into any one particular state, but constrain the state into which the system evolves to lie in a given set, and at the same time fix the probabilities with which the system evolves into the states from the given set. He found this conclusion sufficiently unsettling to

suggest that the entanglement between two separating systems would persist only for distances small enough that the time taken by light to travel from one system to the other could be neglected, compared with the characteristic time periods associated with other changes in the composite system. He speculated that for longer distances each of the two systems might in fact be in a state associated with a certain mixture, determined by the precise form of the entangled state.

Most physicists dismissed the puzzling features of entangled quantum states as an artefact of Einstein's inappropriate ‘detached observer’ view of physical theory, and regarded Bohr's reply to the EPR argument as vindicating the Copenhagen interpretation. This was unfortunate, because the study of entanglement was ignored for thirty years until John Bell's reconsideration and extension of the EPR argument. Bell looked at entanglement in simpler systems than the EPR case: matching correlations between two-valued dynamical quantities, such as polarization or spin, of two separated systems in an entangled state. What Bell showed was that the statistical correlations between the measurement outcomes of suitably chosen *different* quantities on the two systems are inconsistent with an inequality derivable from Einstein's separability and locality assumptions -- in effect from the assumption that the correlations have a common cause.

Bell's investigation generated an ongoing debate on the foundations of quantum mechanics. One important feature of this debate was confirmation that entanglement can persist over long distances(see Aspect *et al*.), thus falsifying Schrödinger's supposition of the spontaneous decay of entanglement as two entangled particles separate. But it was not until the 1980s that physicists, computer scientists, and cryptographers began to regard the non-local correlations of entangled quantum states as a new kind of non-classical resource that could be exploited, rather than an embarrassment to be explained away. (For further discussion of entanglement as a physical resource, including measuring entanglement, and the manipulation and purification of entanglement by local operations, see "The Joy of Entanglement" by Popescu and Rohrlich in Lo, Popescu, and Spiller, or Nielsen and Chuang.)

Exploiting Entanglement: Quantum Teleportation

Consider again Schrödinger's realization that an entangled state could be used to steer a distant particle into one of a set of states, with a certain probability. In fact, this possibility of ‘remote steering’ is even more dramatic than Schrödinger demonstrated. Suppose Alice and Bob share an entangled state of the sort considered by Bell, say two photons in an entangled state of polarization. That is, Alice has in her possession one of the entangled photons, and Bob the other. Suppose that Alice has an additional photon in an unknown state of polarization, *u*. It is possible for Alice to perform an operation on the two photons in her possession that will transform Bob's photon into one of four states, depending on the four possible (random) outcomes of Alice's operation: either the state *u*, or a state that is related to *u* in a definite way. Alice's operation entangles the two photons in her possession, and disentangles Bob's photon, steering it into a state *u**. After Alice communicates the outcome of her operation to Bob, Bob knows either that *u** = *u*, or how to transform *u** to *u* by a local operation. This phenomenon is known as ‘quantum teleportation.’

What is extraordinary about this phenomenon is that Alice and Bob have managed to use their shared entangled state as a quantum communication channel to destroy the state *u* of a photon in Alice's part of the universe and recreate it in Bob's part of the universe. Since the state of a photon requires specifying a direction in space (essentially the value of an angle that can vary continuously), without a shared entangled state Alice would have to convey an infinite amount of classical information to Bob for Bob to be able to reconstruct the state *u* precisely. To see why this is so, consider that the decimal expansion of an angle variable represented by a real number is represented by a potentially infinite sequence of digits between 0 and 9. The binary expansion is represented by a potentially infinite sequence of 0's and 1's. Ever since Shannon formalized the notion of classical information, the amount of classical information associated with a binary alternative (represented as 0 or 1), where each alternative has equal *a priori* probability, is measured as one binary digit or ‘bit’. So to specify the value of an arbitrary angle variable requires an infinite number of bits. To specify the outcome of Alice's operation, which has four possible outcomes, with equal *a priori* probabilities, requires two bits of classical information. Remarkably, Bob can reconstruct the state *u* on the basis of just two bits of classical information communicated by Alice, apparently by exploiting the entangled state as a quantum communication channel to transfer the remaining information. (For further discussion of quantum teleportation, see Nielsen and Chuang, or Richard Josza's article "Quantum Information and its Properties" in Lo, Popescu, and Spiller.)

Quantum Information

Formally, the amount of information we gain, on average, when we learn the value of a random variable (or, equivalently, the amount of uncertainty in the value of a random variable before we learn its value) is represented by a quantity called the Shannon entropy, measured in bits. A random variable is defined by a probability distribution over a set of values. In the case of a binary random variable, with equal probability for each of the two possibilities, the Shannon entropy is 1 bit, representing maximal uncertainty. For all other probabilities -- intuitively, representing some information about which alternative is more likely -- the Shannon entropy is less than 1. For the case of maximal knowledge or zero uncertainty about the alternatives, where the probabilities are 0 and 1, the Shannon entropy is zero.

Since information is always embodied in the state of a physical system, we can also think of the Shannon entropy as quantifying the physical resources required to store classical information. Suppose Alice wishes to communicate some classical information to Bob over a classical communication channel such as a telephone line, say an email message. A relevant question concerns the extent to which the message can be compressed without loss of information, so that Bob can reconstruct the original message accurately from the compressed version. According to Shannon's noiseless coding theorem (assuming a noiseless telephone line with no loss of information), the minimal physical resources required to represent the message (effectively, a lower bound on the possibility of compression) are given by the Shannon entropy of the source.

What happens if we use the quantum states of physical systems to store information, rather than classical states? It turns out that quantum information is radically different from classical information. The unit of quantum information is the ‘qubit’, representing the amount of information that can be stored in the state

of the simplest quantum system, for example, the polarization state of a photon. (The term is due to Schumacher, who proved a quantum analogue of Shannon's noiseless coding theorem.) As we have seen, an arbitrarily large amount of classical information can be encoded in a qubit. This information can be processed and communicated but, because of the peculiarities of quantum measurement, at most one bit can be accessed! According to a theorem by Holevo, the accessible information in a probability distribution over a set of alternative qubits is limited by the von Neumann entropy, which is equal to the Shannon entropy only when the qubits are orthogonal in the space of quantum states, and is otherwise less than the Shannon entropy.

While classical information can be copied or cloned, the quantum ‘no cloning’ theorem (see Dieks, and Wootters and Zurek) asserts the impossibility of cloning an unknown quantum state. To see why, consider how we might construct a classical copying device. A NOT gate is a device that takes a bit as input and produces as output either a 1 if the input is 0, or a 0 if the input is 1. In other words, a NOT gate is a 1-bit gate that flips the input bit. A controlled-NOT gate, or CNOT gate, takes two bits as inputs, a control bit and a target bit, and flips the target bit if and only if the control bit is 1, while reproducing the control bit. (So there are two inputs, the control and target, and two outputs: the control, and either the target or the flipped target, depending on the value of the control.) A CNOT gate functions as a copying device for the control bit if the target bit is set to 0, because the output of the target bit is then a copy of the control bit (i.e., the input 00 produces output 00, and the input 10 produces output 11). Insofar as we can think of a measurement as simply a copying operation, a CNOT gate is the paradigm of a classical measuring device. (Imagine Alice equipped with such a device, with input and output control and target wires, measuring the properties of an unknown classical world. The input control wire is a probe for the presence of absence of a property, represented by a 1 or a 0. The target wire functions as the pointer, which is initially set to 0. The output of the target is a 1 or a 0, depending on the presence or absence of the property.)

Suppose we attempt to use our CNOT gate to copy an unknown qubit. Since the CNOT gate is now understood as a device for processing quantum states, the evolution from input states to output states must be effected by a physical quantum transformation. Now quantum transformations are linear on the linear state space of qubits. Linearity of the state space means that for any two qubit states (call them 0 and 1) that are orthogonal in the space of qubit states, there is a qubit state that is represented by a linear superposition or sum of these orthogonal states, say 0+1 (which will be non-orthogonal to either of these states). Linearity of the transformation means that any transformation must take a qubit state represented by the sum of two orthogonal qubits to a new qubit state that is the sum of the transformed orthogonal qubits. If the CNOT gate succeeds in copying two orthogonal qubits, it cannot succeed in copying a linear superposition of these qubits. Since the gate functions linearly, it must instead produce a state that is a linear superposition of the outputs obtained for the two orthogonal qubits. That is to say, the output of the gate will be represented by a quantum state that is a sum of two terms, where the first term represents the output of the control and target for the first orthogonal qubit, and the second term represents the output of the control and target for the second orthogonal qubit. This could be written as 00+11. This is an entangled state and not the output that would be required by a successful copying operation, where the control and target each outputs the superposed qubit (which could be written as (0+1)(0+1)).

Quantum Cryptography

Linearity prevents the possibility of cloning or measuring an unknown quantum state. Similarly, it can be shown that if Alice sends Bob one of two nonorthogonal qubits, Bob can obtain information about which of these qubits was sent only at the expense of disturbing the state. In general, for quantum information there is no information gain without disturbance. The impossibility of copying an unknown quantum state, or a state that is known to belong to a set of nonorthogonal states with a certain probability, and the existence of a trade-off relation between information gain and state disturbance, is the basis of the application of quantum information to cryptography. There are quantum protocols involving the exchange of classical and quantum information that Alice and Bob can exploit to share a secret random key, which they can then use to communicate privately. (See Lo's article "Quantum Cryptology" in Lo, Popescu, and Spiller.) Any attempt by an eavesdropper, Eve, to monitor the communication between Alice and Bob will be detectable, in principle, because Eve cannot gain any quantum information without some disturbance to the quantum communication channel. Moreover, the ‘no cloning’ theorem prohibits Eve from copying the quantum communications and processing them off-line, so to speak, after she monitors the classical communication between Alice and Bob.

While the difference between classical and quantum information can be exploited to achieve successful key distribution, there are other cryptographic protocols that are thwarted by quantum entanglement. Bit commitment is a key cryptographic protocol that can be used as a subroutine in a variety of important cryptographic tasks. In a bit commitment protocol, Alice supplies an encoded bit to Bob. The information available in the encoding should be insufficient for Bob to ascertain the value of the bit, but sufficient, together with further information supplied by Alice at a subsequent stage when she is supposed to reveal the value of the bit, for Bob to be convinced that the protocol does not allow Alice to cheat by encoding the bit in a way that leaves her free to reveal either 0 or 1 at will.

To illustrate the idea, suppose Alice claims the ability to predict advances or declines in the stock market on a daily basis. To substantiate her claim without revealing valuable information (perhaps to a potential employer, Bob) she suggests the following demonstration: She proposes to record her prediction, before the market opens, by writing a 0 (for ‘decline’) or a 1 (for ‘advance’) on a piece of paper, which she will lock in a safe. The safe will be handed to Bob, but Alice will keep the key. At the end of the day's trading, she will announce the bit she chose and prove that she in fact made the commitment at the earlier time by handing Bob the key. Of course, the key-and-safe protocol is not provably secure from cheating by Bob, because there is no principle of classical physics that that prevents Bob (if he is an ’ideal’ safe-cracker) from opening the safe and closing it again without leaving any traces. The question is whether there exists a quantum analogue of this procedure that is unconditionally secure: provably secure by the laws of physics against cheating by either Alice or Bob. Bob can cheat if he can obtain *some* information about Alice's commitment before she reveals it (which would give him an advantage in repetitions of the protocol with Alice). Alice can cheat if she can delay actually making a commitment until the final stage when she is required to reveal her commitment, or if she can change her commitment at the final stage with a very low probability of detection.

It turns out that unconditionally secure two-party bit commitment, based solely on the principles of quantum or classical mechanics (without exploiting special relativistic signalling constraints, or principles of general relativity or thermodynamics) is impossible. (See Mayers, Lo and Chau, and Lo's article "Quantum Cryptology" in Lo, Popescu, an Spiller for further discussion. Note that Kent has shown that one can implement a secure classical bit commitment protocol by exploiting relativistic signalling constraints in a timed sequence of communications between verifiably separated sites for both Alice and Bob.) Roughly, the impossibility arises because at any step in the protocol where either Alice or Bob is required to make a determinate choice (perform a measurement on a particle in the quantum channel, choose randomly and perhaps conditionally between a set of alternative actions to be implemented on the particle in the quantum channel, etc.), the choice can delayed by entangling one or more ‘ancilla’ (helper) particles with the channel particle in an appropriate way. By suitable operations on the ancillas, the channel particle can be ‘steered’ so that this cheating strategy is undetectable. In effect, if Bob can obtain no information about the bit in the safe, then entanglement will allow Alice to ‘steer’ the bit to either 0 or 1 at will.

Quantum Computation

Quantum information can be processed, but the accessibility of this information is limited by the Holevo bound. David Deutsch first showed how to exploit quantum entanglement to perform a computational task that is impossible for a classical computer. Suppose we have a black box that evaluates a function *f*. The arguments of *f* (inputs) are either 0 or 1. The values (outputs) of *f* (which are also 0 or 1) are either the same for both arguments (in which case *f* is constant), or different for the two arguments (in which case *f* is said to be ‘balanced’). We are interested in determining whether *f* is constant or balanced. Now, classically, the only way to do this is to run the black box twice, for both arguments 0 and 1, and to pass the values (outputs of *f*) to a circuit that determines whether they are the same (for ‘constant’) or different (for ‘balanced’). Deutsch showed that if we use quantum states and quantum gates to store and process information, then we can determine whether *f* is constant or balanced in one evaluation of the function *f*. The trick is to design the circuit (the sequence of gates) to produce the answer to a *global* question about the function (’constant’ or ‘balanced’) in an output qubit register that can then be read out or measured.

Consider again the quantum CNOT gate, with two orthogonal qubits 0 and 1 as possible inputs for the control, and 0 as the input for the target. Once can think of the input control and output target qubits, respectively, as the argument and associated value of a function. This CNOT function associates the value 0 with the argument 0 and the value 1 with the argument 1. For a linear superposition of the orthogonal qubits, say 0+1, as inut to the control, and the qubit representing 0 as the input to the target, the output is the entangled state 00+11, a linear superposition in which the first term represents the argument 0 and associated value (0) of the CNOT function, and the second term represents the argument 1 and associated value (1) of the CNOT function. The entangled state represents all possible arguments and corresponding values of the function as a linear superposition, but this information is not accessible. What can be shown to be accessible, by a suitable choice of quantum gates, is information about whether or not the function has certain global properties. This information is obtainable without reading out the

evaluation of any individual arguments and values. (Indeed, accessing information in the entangled state about a global property of the function will typically require losing access to all information about individual arguments and values.)

The situation is analogous for Deutsch's function *f*. Here the output of *f* can be represented as either 00 + 10 or 01 + 11 (in the ‘constant’ case), or 00 + 11 or 01 + 10 (in the ‘balanced’ case). The two entangled states in the ‘constant’ case are orthogonal in the 4-dimensional two-qubit state space and span a plane. Call this the ‘constant’ plane. Similarly, the two entangled states in the ‘balanced’ case span a plane, the ‘balanced’ plane. These planes are orthogonal in the 4-dimensional state space, except for an overlap: a line, representing a (non-entangled) two-qubit state. It is therefore possible to design a measurement to distinguish the two global properties of *f*, ‘constant’ or ‘balanced,’ with a certain probability (actually, 1/2) of failure, when the measurement yields an outcome corresponding to the overlap state, which is common to the two cases. Nevertheless, only one query of the function is required when the measurement succeeds in identifying the global property. With a judicious choice of quantum gates, it is even possible to design a quantum circuit that always succeeds in distinguishing the two cases.

Deutsch's example shows how quantum information, and quantum entanglement, can be exploited to compute a global property of a function in one step that would take two steps classically. In general, though, the potential speed-up in quantum computation relative to classical computation is exponential. Essentially, this is again due to the phenomenon of entanglement. Indeed, the amount of information required to describe a general entangled state of n qubits grows exponentially with n. The state space (Hilbert space) has 2^n dimensions, so a general entangled state is a superposition of 2^n n-qubit states. In classical mechanics there are no entangled states: a general n-bit composite system can be described with just n times the amount of information required to describe a single bit system. So the classical simulation of a quantum process would involve an exponential increase in the classical informational resource required to represent the quantum state, as the number of qubits that become entangled in the evolution grows linearly, and there would be a corresponding exponential slowdown in calculating the evolution, compared to the actual quantum computation performed naturally by the system.

While Deutsch's problem is in a sense trivial and has no interesting application, there now exist several quantum algorithms for non-trivial problems, notably Shor's factorization algorithm for factoring large composite integers in polynomial time (with direct application to ‘public key’ cryptography, a widely used classical cryptographic scheme) and Grover's database search algorithm. (See Nielsen and Chuang, or Barenco's article "Quantum Computation: An Introduction" in Lo, Popescu, and Spiller for details.)

Interpretative Remarks

The explanation favoured by Deutsch and others of how a quantum system processes information is the so-called ‘many-worlds’ interpretation. The idea, roughly, is that an entangled state of the sort that arises in the quantum computation of a function, which represents a linear superposition over all possible arguments and corresponding values of the function, should be understood as a manifestation of parallel computations in different worlds. The quantum circuit is designed to enable the computation of a global

property of the function by achieving some sort of 'interference' between these different worlds. (For an insightful critique of this idea of 'quantum parallelism' as explanatory, see Steane. It should be noted that the term 'many-worlds' can refer to a variety of interpretational ideas, some more refined than others.)

An alternative view, not much discussed in the literature in this connection, is the quantum logical interpretation, which emphasizes the non-Boolean structure of properties of quantum systems. (The properties of a classical system form a Boolean algebra, essentially the abstract characterization of a set-theoretic structure. This is reflected in the Boolean character of classical logic, and the Boolen gates in a classical computer.) A crucial difference between quantum and classical information is the possibility of computing the truth value of an exclusive disjunction -- for example, the 'constant' disjunction asserting that the value of the function (for both arguments) is either 0 or 1, or the 'balanced' disjunction asserting that the value of the function (for both arguments) is either the same as the argument or different from the argument -- without computing the truth values of the disjuncts. Classically, an exclusive disjunction is true if and only if one of the disjuncts is true. In effect, Deutsch's quantum circuit achieves its speed-up by exploiting the non-Boolean structure of quantum properties to compute the value of a disjunctive property, without computing the value of the disjuncts (representing the association of individual arguments with corresponding function values).

Reichenbach's Common Cause Principle

Suppose that two geysers, about one mile apart, erupt at irregular intervals, but usually erupt almost exactly at the same time. One would suspect that they come from a common source, or at least that there is a common cause of their eruptions. And this common cause surely acts before both eruptions take place. This idea, that simultaneous correlated events must have prior common causes, was first made precise by Hans Reichenbach (Reichenbach 1956). It can be used to infer the existence of unobserved and unobservable events, and to infer causal relations from statistical relations. Unfortunately it does not appear to be universally valid, nor is there agreement as to the circumstances in which it is valid.

Reichenbach's Common Cause Principle

It seems that a correlation between events A and B indicates either that A causes B, or that B causes A, or that A and B have a common cause. It also seems that causes always occur before their effects and, thus, that common causes always occur before the correlated events. Reichenbach was the first to formalize this idea rather precisely. He suggested that when Pr(A&B) > Pr(A)xPr(B) for simultaneous events A and B, there exists an earlier common cause C of A and B, such that Pr(A/C) > Pr(A/~C), Pr(B/C) > Pr(B/~C), Pr(A&B/C) = Pr(A/C)xPr(B/C) and Pr(A&B/~C) = Pr(A/~C)xPr(B/~C). (See Reichenbach 1956 pp. 158-159.) C is said to ‘screen off´ the correlation between A and B when A and B are uncorrelated conditional upon C. Thus Reichenbach´s principle can also be formulated as follows: simultaneous correlated events have a prior common cause that screens off the correlation.[1, 2]

Reichenbach's common cause principle needs to be modified. Consider, for instance, the following example. Harry normally takes the 8 a.m. train from New York to Washington. But he does not like full trains, so if the 8 a.m. train is full he sometimes takes the next train. He also likes trains that have diner cars, so if the 8 a.m. train does not have a diner car he

sometimes takes the next train. If the 8 a.m. train is both full and has no diner car, he is very likely to take the next train. Johnny, an unrelated commuter, also normally takes the 8 a.m. train from New York to Washington. Johnny, it so happens, also does not like full trains, and he also likes diner cars. Whether or not Harry and Johnny take the 8 a.m. train will therefore be correlated. But, since the probability of Harry and Johnny taking the 8 a.m. train depends on the occurrence of two distinct events (the train being full, the train having a diner car) there is no single event C, such that conditional upon C and conditional upon ~C we have independence. Thus Reichenbach's common cause principle as stated above is violated. Yet this example clearly does not violate the spirit of Reichenbach's common cause principle, for there is a partition into four possibilities such that conditional upon each of these four possibilities the correlation disappears.

More generally, we would like to have a common cause principle for cases in which the common causes and the effects are sets of quantities with continuous or discrete sets of values, rather than single events that occur or do not occur. A natural way to modify Reichenbach's common cause principle in order to deal with such types of cases is as follows. If simultaneous values of quantities A and B are correlated, then there are common causes C_1, C_2,....., C_n, such that conditional upon any combination of values of these quantities at an earlier time, the values of A and B are probabilistically independent. (For a fuller discussion of modifications like this, including cases in which there are correlations between more than two quantities, see Uffink (forthcoming)). I will continue to call this generalization ‘Reichenbach's common cause principle’, since, in spirit, it is very close to the principle that Reichenbach originally stated.

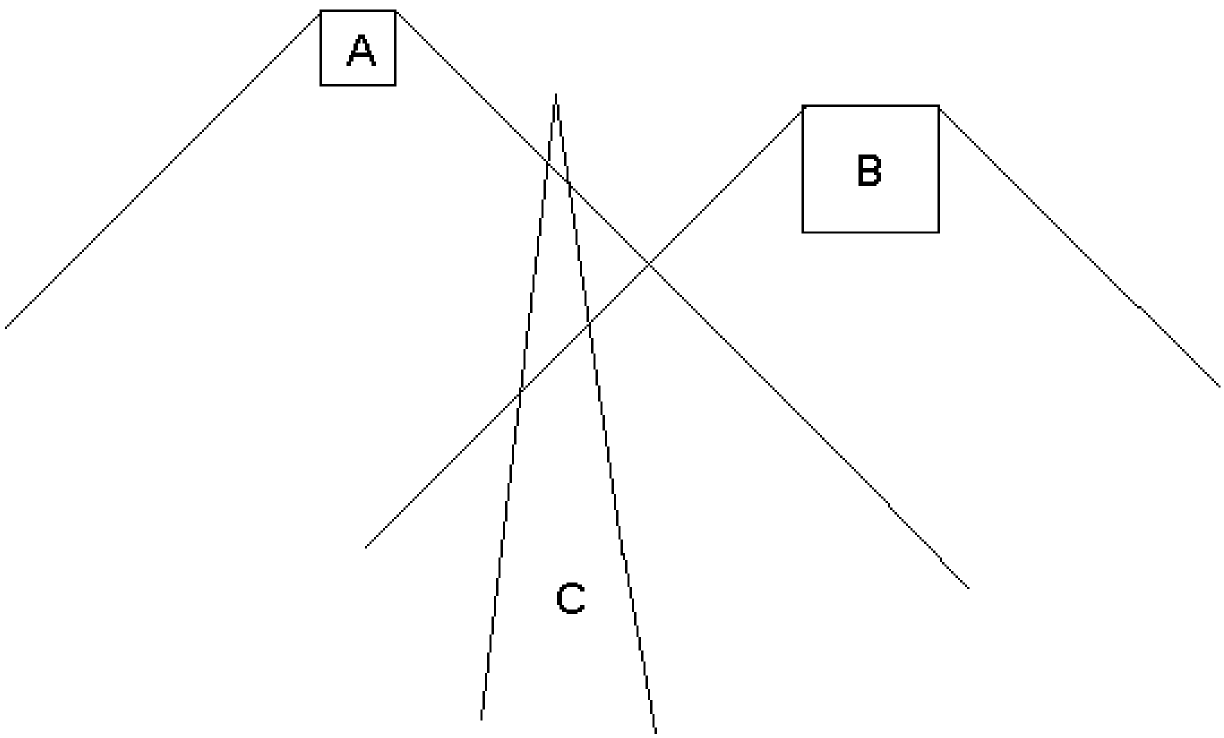
Now let me turn to two principles, the ‘causal Markov condition’ and the ‘law of conditional independence’, that are closely related to Reichenbach's common cause principle.

The Causal Markov Condition

There is a long tradition of attempts to infer causal relations among a set of quantities from probabilistic facts about the values of these quantities. In order to be able to do so, one needs principles relating causal facts and probabilistic facts. A principle that has been used to great effect in Spirtes, Glymour & Scheines 1993, is the ‘causal Markov condition’. This principle holds of a set of quantities $\{Q_1,......,Q_n\}$ if and only if the values of any quantity Q_i in that set, conditional upon the values of all the quantities in the set that are direct causes of Q_i, are probabilistically independent of the values of all quantities in the set other than Q_i's effects.[3] The causal Markov condition implies the following version of the common cause principle: If Q_i and Q_j are correlated and Q_i is not a cause of Q_j, and Q_j is not a cause of Q_i, then there are common causes of Q_i and Q_j in the set $\{Q_1,......,Q_n\}$ such that Q_i and Q_j are independent conditional upon these common causes.[4]

The Law of Conditional Independence

Penrose and Percival (1962), following Costa de Beauregard, have suggested as a general principle that the effects of interactions are felt after those interactions rather than before. In particular, they suggest that a system that has been isolated throughout the past is uncorrelated with the rest of the universe. Of course, this is almost a vacuous claim, since, other than in the case of horizons in cosmology, there would not appear to be a surfeit of systems that have been completely isolated from the rest of the universe throughout the past. Penrose and Percival, however, strengthen their principle by claiming that if one sets up a ‘statistical barrier’ that prevents any influences from acting both upon a space-time region A and a space-time region B, then states a in A and b in B will be uncorrelated. Penrose and Percival use the assumption that influences can not travel faster than the speed of light to make this idea more precise. Consider a space-time region C where there is no point P to the past of A or B such that one can travel, at a speed no faster than the speed of light, both from P to A and from P to B without entering C.



Penrose and Percival then say that one can prevent any influence from acting on both A and B by fixing the state c throughout such a region C. They therefore claim that states a in A and b in B will be uncorrelated conditional upon any state c in C. To be precise, they suggest the ‘law of conditional independence’: "If A and B are two disjoint 4-regions, and C is any 4-region which divides the union of the pasts of A and B into two parts, one containing A and the other containing B, then A and B are conditionally independent given c. That is, Pr(a&b/c) = Pr(a/c)xPr(b/c), for all a,b." (Penrose and Percival 1962, p. 611).

This is a time asymmetric principle which is clearly closely related to Reichenbach's common cause principle and the causal Markov condition. However one should not take states c in region C to be, or include, the common causes of the (unconditional) correlations that might exist between the states in regions A and B. It is merely a region such that influences from a past common source on both A and B must pass through it, assuming that such influences do not travel at speeds exceeding the speed of light. Note also that the region must stretch to the beginning of time. Thus, one cannot derive anything like Reichenbach's common cause principle or the causal Markov condition from the law of conditional independence, and one therefore would not inherit the richness of applications of these principles, especially the causal Markov condition, even if one were to accept the law of conditional independence.

Let us now turn to reasons that have been given for not believing any of these principles.

Conserved Quantities, Indeterminism and Quantum Mechanics

Suppose that a particle decays into 2 parts, that conservation of total momentum obtains, and that it is not determined by the prior state of the particle what the momentum of each part will be after the decay. By conservation, the momentum of one

part will be determined by the momentum of the other part. By indeterminism, the prior state of the particle will not determine what the momenta of each part will be after the decay. Thus there is no prior screener off. By simultaneity and symmetry, it is implausible to suppose that the momentum of the one part causes the momentum of the other part. So common cause principles fail. (This example is from van Fraassen (1980), page 29.)

More generally, suppose that there is a quantity Q, which is a function $f(q_1,....,q_n)$ of quantities q_i. Suppose that some of the quantities q_i develop indeterministically, but that quantity Q is conserved in such developments. There will then be correlations among the values of the quantities q_i which have no prior screener off. The only way that common cause principles can hold when there are conserved global quantities is when the development of each of the quantities that jointly determine the value of the global quantity is deterministic. And then it holds in the trivial sense that the prior determinants make everything else irrelevant. The results of quantum mechanical measurements are not determined by the quantum mechanical state prior to those measurements. And often there are conserved quantities during such a measurement. For instance, the total spin of 2 particles in a quantum 'singlet' state is 0. This quantity is conserved when one measures the spins of each of those 2 particles in the same direction: one will always find opposite spins during such a measurement, i.e. the spins that one finds will be perfectly anti-correlated. However what spins one will find is not determined by the prior quantum state. Thus the prior quantum state does not screen off the anti-correlations. There is no quantum common cause of such correlations.

One might think that this violation of common cause principles is a reason to believe that there must then be more to the prior state of the particles than the quantum state; there must be 'hidden variables' that screen off such correlations. (And we have seen above that such hidden variables must determine the results off the measurements if they are to screen of the correlations.) However, one can show, given some extremely plausible assumptions, that there cannot be any such hidden variables. (See, for instance, van Fraassen 1982 and Elby 1992 for more detail.)

One can also show that such correlations without a possible prior screener off are not confined to very special states, but occur generically in quantum mechanics and quantum field theory. (See Redhead (1995), Clifton, Feldman, Halvorson, Redhead & Wilce (1998), and Clifton & Ruetsche (forthcoming).)

Electromagnetism; Laws of Coexistence

Maxwell's equations not only govern the development of electromagnetic fields, they also imply simultaneous (in all frames of reference) relations between charge distributions and electromagnetic fields. In particular they imply that the electric flux through a surface which encloses some region of space must equal the total charge in that region. Thus electromagnetism implies that there is a strict and simultaneous correlation between the state of the field on such a surface and the charge distribution in the region contained by that surface. And this correlation must hold even on the space-like boundary at the beginning of the universe (if there be such). This violates all three common cause principles. (For more detail and subtlety, see Earman 1995, chapter 5).

More generally, any coexistence law, such as Newtonian gravitation, or Pauli's exclusion principle, will imply correlations which have no prior common cause conditionally upon which they disappear. Therefore, contrary to what one might hope, there are relativistic co-existence laws which violate common cause principles.

Bread and Water; Similar Laws of Evolution

The bread prices in Britain have been going up steadily over the last few centuries. The water levels in Venice have been going up steadily over the last few centuries. There is therefore a correlation between (simultaneous) bread prices in Britain and sea levels in Venice. However, there is presumably no direct causation involved, nor a common cause. More generally, Elliot Sober (see Sober 1988) has suggested that similar laws of evolution of otherwise independent quantities can lead to

correlations for which no common cause exists.

There is a way of understanding common cause principles such that this example is not a counterexample to it. Suppose that in nature there are transition chances from values of quantities at earlier times to values of quantities at later times. (For more in this idea see Arntzenius 1997). One could then state a common cause principle as follows: conditional upon the values of all the quantities upon which the transition chances to quantities X and Y depend, X and Y will be probabilistically independent. In Sober's example, there are transition chances from earlier costs of bread to later costs of bread, and there are transition chances from earlier water levels to later water levels. Conditional upon earlier costs of bread, later costs of bread are independent of later water levels. A common cause principle formulated as above thus holds in this case. Of course, if one looks at a collection of (simultaneous) data for water levels and bread prices one will see a correlation due to similar laws of development (similar transition chances). But a common cause principle, understood in terms of transition chances, does not imply that there should be a common cause of this correlation. The data (which include these correlations) should be understood as evidence for what the transition chances in nature are, and it is those transition chances that could be demanded to satisfy a common cause principle.

Markov Processes

Suppose a particular type of object has 4 possible states: S_1, S_2, S_3 and S_4. Suppose that if such an object is in state S_i at time t, and is not interfered with (isolated), then at time t+1 it has probability ½ of being in the same state S_i, and probability ½ of being in state S_i+1, where we define 4 + 1 = 1 (i.e. '+' represents addition mod 4). Now suppose we put many such objects in state S_1 at time t = 0. Then at time t = 1 approximately half of the systems will be in state S_1, and approximately half will be in state S_2. Let us define property A to be the property that obtains precisely when the system is either in state S_2 or in state S_3, and let us define property B to be the property that obtains precisely when the system is either in state S_2 or in state S_4. At time t = 1 half of the systems are in state S_1, and therefore have neither property A nor property B, and the other half are in state S_2, so that they have both property A and property B. Thus A and B are perfectly correlated at t = 1. Since these correlations remain conditional on the full prior state (S_1), there can be no quantity such that conditional upon a prior value of this quantity A and B are uncorrelated. Thus all three principles fail in this case. One can generalize this example to all generic state-space processes with indeterministic laws of developments, namely Markov processes. At least, one can do this if one allows arbitrary partitions of state-space to count as quantities. (In particular, therefore, Markov processes generically do not satisfy the causal Markov condition. The similarity of names is thus a bit misleading. See Arntzenius 1993 for more detail.)

Deterministic Systems

Suppose that the state of the world (or a system of interest) at any time determines the state of the world (that system) at any other time. It then follows that for any quantity X (of that system) at any time *t*, there will be at any other time t', in particular any later time t', a quantity X' (to be precise: a partition of state-space) such that the value of X' at t' uniquely determines the value of X at *t*. Conditional upon the value of X' at t', the value of X at *t* will be independent of any value of any quantity at any time. (For more detail see Arntzenius 1993.) Reichenbach's common cause principle thus fails in deterministic contexts. The problem is not that there will not always be earlier events conditional upon which the correlations disappear. Conditional upon the deterministic causes all correlations disappear. The problem is that there will also always be later events that determine whether the earlier correlated events occur. Reichenbach's common cause principle thus fails in so far as it claims that typically there are no later events conditional upon which earlier correlated simultaneous events are uncorrelated.

This does not imply a violation of the causal Markov condition. However, in order to be able to infer causal relations from statistical ones, Spirtes, Glymour and Scheines in effect assume that whenever (unconditionally correlated) quantities Q_i and

Q_j are independent conditional upon some quantity Q_k, then Q_k is a cause of either Q_i or Q_j. To be more precise they assume the ‘Faithfulness condition’, which states that there are no probabilistic independencies in nature other than the ones entailed by the causal Markov condition. Since the values of such quantities X' at later times t' surely are not direct causes of X at *t*, Faithfulness is violated, and with it goes our ability to infer causal relations from probabilistic relations, and much of the practical value of the causal Markov condition.[5]

A quantity like X' whose values at a later time t' are deterministically related to the values of X at *t*, will in general correspond to a non-natural, non-local, and not directly observable quantity. Perhaps a common cause principle can hold of some natural class of quantities. However, the next two sections will show that two suggestions for such a natural class do not work.

Macroscopic Quantities

Cleopatra is throwing a big party, and wants to sacrifice around fifty slaves to appease the gods. She is having a hard time convincing the slaves that this is a good idea, and decides that she ought to give them a chance at least. She has obtained a very strong poison, so strong that one molecule of it will kill a person. She puts one molecule of the poison in each of a hundred goblets of wine, which she presents to one hundred slaves. Having let the molecules of poison move around in Brownian motion for a while, she then orders the slaves to drink half a goblet of wine each. Let us now assume that if one consumes the poison, then death is preceded by an ominous reddening of the left hand and of the right hand. Then, the molecule being in the consumed half of the wine glass will be a prior screener off of the correlation between left hand reddening and right hand reddening. Assuming that death occurs exactly in the cases that the poison is swallowed, death will be a posterior screener off. If one restricts oneself to macroscopic events, there will only be a posterior screener off. If death is not strictly determined by the swallowing or non-swallowing of the poison, there will be no macroscopic screener off at any time. Thus, if microscopic events can have such macroscopic consequences, a common cause principle cannot hold of macroscopic events. More generally, this argument suggests that the common cause principle cannot hold of a class of events that has causes outside that class. This argument appears even more forceful for those who believe that the only reason that we can acquire knowledge of microscopic events and microscopic laws, is precisely the fact that microscopic events, in certain situations, have effects upon observable events.

Let us now consider another type of counterexample to the idea that a common cause principle can hold of macroscopic quantities, namely cases in which order arises out of chaos. When one lowers the temperature of certain materials, the spins of all the atoms of the material, which originally are not aligned, will line up in the same direction. Pick any two atoms in this structure. Their spins will be correlated. However, it is not the case that the one spin orientation caused the other spin orientation. Nor is there a simple or macroscopic common cause of each orientation of each spin. The lowering of the temperature determines that the orientations will be correlated, but not the direction in which they will line up. Indeed, typically, what determines the direction of alignment, in the absence of an external magnetic field, is a very complicated fact about the total microscopic prior state of the material and the microscopic influences upon the material. Thus, other than virtually the complete microscopic state of the material and its environment there is no prior screener off of the correlation between the spin alignments.

In general when chaotic developments result in ordered states there will be final correlations which have no prior screener off, other than virtually the full microscopic state of the system and its environment. (For more examples, see Prigogine 1980). In such cases the only screener off will be a horrendously complex microscopic quantity.

Local Quantities

If a common cause principle does not hold when one restricts oneself to macroscopic quantities, perhaps it holds if one restricts oneself to local quantities? Let me show that this is not so by giving a counterexample. There is a correlation between the take-off time of airplanes at airports and the time clothes take to dry on washing lines in any city near those

airports. An apparently satisfactory common cause explanation of this phenomenon is that high humidity causes both long drying times and long take-off times. However, this explanation presupposes that the humidity at the airport and at nearby houses is correlated. Now, it is not the case that the humidity in one area directly causes the humidity in other nearby areas. Moreover, there is no local common cause of the correlation among humidities in nearby areas, for there is no local earlier quantity that determines the humidity at separated locations at later times. Rather, the explanation of the correlation between the humidities in quite widely separated areas is that, when the total system is in (approximate) equilibrium then the humidity in different areas is (approximately) identical. Indeed the world is full of (approximate) equilibrium correlations, without local common causes conditional upon which these correlations disappear. (For more examples of this type of case see Forster 1986).

Next consider a flock of birds that flies, more or less, like a single unit in a rather varied trajectory through the sky. The correlation between the motions of each bird in the flock could have a rather straightforward common cause explanation: there could be a leader bird that every other bird follows. But it could also be that there is no leader bird, that each bird reacts to certain factors in the environment (presence of predator birds, insects, etc.), while at the same time constraining the distance that it will remove itself from its neighboring birds in the flock (as if tied to them by springs that pull harder the further away it gets from the other birds). In the latter case there will be a correlation of motions for which there is no local common cause. There will be an 'equilibrium' correlation that is maintained in the face of external perturbations. In 'equilibrium' the flock acts more or less as a unit, and reacts as a unit, possibly in a very complicated way, in response to its environment. The explanation of the correlation among the motions of its parts is not a common cause explanation, but the fact that in 'equilibrium' the myriad connections between its parts make it act as a unit.

In general we have learned to divide the world into systems which we regard as single units, since their parts normally (in 'equilibrium') behave in a highly correlated manner. We routinely do not regard correlations among the motions and properties of the parts of these systems as demanding a common cause explanation.

Initial Microscopic Chaos and the Common Cause Principle

Many authors have noted that there are circumstances in which the causal Markov condition, and the common cause principle that it implies, provably holds. Roughly speaking, this is the case when the world is deterministic, and the factors A and B which, in addition to the common cause C, determine whether effects D and E occur, are uncorrelated. Let me be more general and precise. Consider a deterministic world and a set of quantities S with certain causal relations holding between them. For any quantity Q, let us call the factors not in S which, when combined with the direct causes of Q that are in S, determine whether Q occurs, the 'determinants of Q outside S'. Suppose now that the determinants outside S are all independent, i.e. that the joint distribution of all determinants outside S is a product of distributions for each such determinant outside S. One can then prove that the causal Markov condition holds in S.[6]

But when should one expect such independence? P. Horwich (Horwich 1987) has suggested that such independence follows from initial microscopic chaos. (See also Papineau 1985 for a similar suggestion.) His idea is that if all the determinants outside S are microscopic, then they will all be uncorrelated since all microscopic factors will be uncorrelated when they are chaotically distributed. However, even if one has microscopic chaos (i.e. a uniform probability distribution in certain parts of state-space in a canonical coordinatization of the state-space), it is still not the case that all microscopic factors are uncorrelated. Let me give a generic counterexample.

Suppose that quantity C is a common cause of quantities A and B, that the system in question is deterministic, and that the quantities a and b which, in addition to C, determine the values of A and B are microscopic and independently distributed for each value of C. Then A and B will be uncorrelated conditional upon each value of C. Now define quantities D:A+B and E:A-B. ("+" and "-" here represent ordinary addition and subtraction of the values of quantities.) Then, generically, D and E will be correlated conditional upon each value of C. To illustrate why this is so let me give a very simple example. Suppose that for a given value of C quantities A and B are independently distributed, that A has value 1 with probability 1/2 and

value -1 with probability 1/2, and that B has value 1 with probability 1/2 and value -1 with probability 1/2. Then the possible values of D are -2, 0 and 2, with probabilities 1/4, 1/2 and 1/4 respectively. The possible values of E are also -2, 0 and 2, with probabilities 1/4, 1/2 and 1/4 respectively. But note, for instance, that if the value of D is -2, then the value of E must be 0. In general a non-zero value for D implies value 0 for E and a non-zero value for E implies value 0 for D. Thus, the values of D and E are strongly correlated for the given value of C. And it is not too hard to show that, generically, if quantities A and B are uncorrelated, then D and E are correlated. Now, since D and E are correlated conditional upon any value of C, it follows that C is not a prior common cause which screens off the correlation between D and E. And since the factors a and b which, in addition to C, determine the values of A and B, and hence those of D and E, can be microscopic and horrendously complex, there will be no screener off of the correlations between D and E other than some incredibly complex and inaccessible microscopic determinant. Thus common cause principles fail if one uses quantities D and E rather than quantities A and B to characterize the later state of the system.

One might try to save common cause principles by suggesting that in addition to C being a cause of D and of E, D is also a cause of E, or E is also a cause of D. (See Glymour and Spirtes 1994, pp 277-278 for such a suggestion). This would explain why D and E are still correlated conditional upon C. Nonetheless, this does not seem a plausible suggestion. In the first place, D and E are simultaneous. In the second place, the situation sketched is symmetric with respect to D and E, so which is supposed to cause which? It seems far more plausible to admit that common cause principles fail if one uses quantities D and E.

One might next try to defend common cause principles by suggesting that D and E are not really independent quantities, given that each is defined in terms of A and B, and that one should only expect common cause principles to be true of good, honest, independent quantities. Although this argument is along the right lines, as it stands it is too quick and simple. One cannot say that D and E are not independent because of the way they are defined in terms of A and B. For similarly A = ½(D+E) and B = ½(D-E), and unless there are reasons independent of such equations to claim that A and B are bona fide independent quantities while D and E are not, one is stuck. For now let us therefore conclude that an attempt to prove the common cause principle by assuming that all microscopic factors are uncorrelated rests on a false premise.

Nonetheless such arguments are pretty close to being correct: microscopic chaos does imply that a very large and useful class of microscopic conditions are independently distributed. For instance, assuming a uniform distribution of microscopic states in macroscopic cells, it follows that the microscopic states of two spatially separated regions will be independently distributed, given any macroscopic states in the two regions. Thus microscopic chaos and spatial separation is sufficient to provide independence of microscopic factors. This in fact covers a very large and useful class of cases. For almost all correlations that we are interested in are between factors of systems that are not exactly in the same location. Consider, for instance, an example due to Reichenbach.

Suppose that two actors almost always eat the same food. Every now and then the food will be bad. Let us assume that whether or not each of the actors become sick depends on the quality of the food that they consume and on other local factors (properties of their body etc.) at the time of consumption (and perhaps also later), which previously have developed chaotically. The values of these local factors for one of the actors will then be independent of the values of these local factors for the other actor. It then follows that there will be a correlation between their states of health, and that this correlation will disappear conditional upon the quality of the food. In general when one has a process that physically splits into two separate processes which remain separated in space, then all the ‘microscopic’ influences on those two processes will be independent from then on. Indeed there are very many cases in which two processes, whether spatially separated or not, will have a point after which microscopic influences on the processes are independent given microscopic chaos. In such cases common cause principles will be valid as long as one chooses as one's quantities the (relevant aspects of the) macroscopic states of the processes at the time of such separations (rather than the macroscopic states significantly prior to such separations) and some aspects of macroscopic states somewhere along each separate process (rather than some amalgam of quantities of the separate processes).

Conjectural and Provocative Conclusions

Reichenbach's principle of the common cause and its cousins, insofar as they hold, have the same origin as the temporal asymmetries of statistical mechanics, namely, roughly speaking, initial microscopic chaos. (I am being very rough here. There is no absolute, dynamics independent, distinction between microscopic and macroscopic factors. For more detail on exactly which quantities will behave as if they are uniformly distributed in which circumstances see, e.g., D. Albert (1999).) This explains why the three principles we have discussed sometimes fail. For the demand of initial microscopic chaos is a demand that microscopic conditions are uniformly distributed (in canonical coordinates) in the areas of state-space that are compatible with the fundamental laws of physics. If there are fundamental (equal time) laws of physics that rule out certain areas in state-space, which thus imply that there are (equal time) correlations among certain quantities, this is no violation of initial microscopic chaos. But the three common cause principles that we discussed will fail for such correlations. Similarly, quantum mechanics implies that for certain quantum states there will be correlations between the results of measurements that can have no common cause which screens all these correlations off. But this does not violate initial microscopic chaos. Initial microscopic chaos is a principle that tells one how to distribute probabilities over quantum states in certain circumstances; it does not tell one what the probabilities of values of observables given certain quantum states should be. And if they violate common cause principles, so be it. There is no fundamental law of nature that is, or implies, a common cause principle. The extent of the truth of common cause principles is approximate and derivative, not fundamental.

One should also not be interested in common cause principles which allow any conditions, no matter how microscopic, scattered and unnatural, to count as common causes. For, as we have seen, this would trivialize such principles in deterministic worlds, and would hide from view the remarkable fact that when one has a correlation among fairly natural localized quantities that are not related as cause and effect, almost always one can find a fairly natural, localized prior common cause that screens off the correlation. The explanation of this remarkable fact, which was suggested in the previous section, is that Reichenbach's common cause principle, and the causal Markov condition, must hold if the determinants, other than the causes, are independently distributed for each value of the causes. The fundamental assumptions of statistical mechanics imply that this independence will hold in a large class of cases given a judicious choice of quantities characterizing the causes and effects. In view of this, it is indeed more puzzling why common cause principles fail in cases like those described above, such as the coordinated flights of certain flocks of birds, equilibrium correlations, order arising out of chaos, etc. The answer is that in such cases the interactions between the parts of these systems are so complicated, and there are so many causes acting on the systems, that the only way one can get independence of further determinants is by specifying so many causes as to make this a practical impossibility. This, in any case, would amount to allowing just about any scattered and unnatural set of factors to count as common causes, thereby trivializing common cause principles. Thus, rather than do that, we regard such systems as single unified systems, and do not demand a common cause explanation for the correlated motions and properties of their parts. A fairly intuitive notion of what counts as a single system, after all, is a system that behaves in a unified manner, i.e. a system whose parts have a very strong correlation in their motions and/or other properties, no matter how complicated the set of influences acting on them. For instance a rigid physical object has parts whose motions are all correlated, and a biological organism has parts whose motions and properties are strongly correlated, no matter how complicated the influences acting on it. These systems therefore are naturally and usefully treated as single systems for almost any purpose. The core truth of common cause principles thus in part relies on our choice as to how to partition the world into unified and independent objects and quantities, and in part on the objective, temporally asymmetric, principles that lie at the foundation of statistical mechanics.

Notes to Reichenbach's Common Cause Principle

Notes

1. Reichenbach's common cause principle is a time-asymmetric principle. One could make this asymmetry more explicit by adding the claim that, typically, there are no later events E conditional upon which A and B are uncorrelated. As with all time-asymmetric principles, one might wonder whether nature really does exhibit such an asymmetry, and if indeed it does, what its origin is, and how it relates to other temporal asymmetries. Reichenbach himself wanted to use the common cause asymmetry as part of a definition of the distinction between the future and the past. On his view, then, it is not interesting to ask why a common cause C occurs before its effects A and B; for that is true by definition of the direction of time. But on his view it remains an interesting question as to why all common causes are always placed in the same direction of time relative to their effects, and how this asymmetry relates to other temporal asymmetries such as thermodynamic asymmetries.

2. One might wish to understand the probabilistic relations stated in this principle as a definition of what a common cause is. However, this is not a plausible idea. For, consider a case in which A_1 is a common cause of A_2 and A_3, while A_2 in its turn causes A_4, and A_3 in its turn causes A_5, where A_4 and A_5 are simultaneous. In this case A_4 and A_5 will typically be uncorrelated conditional upon A_2 (assuming that A_2 is the only cause of A_4). Moreover, an occurrence of A_2 will typically make an occurrence of A_4 more likely, and, typically, it will make an occurrence of A_5 more likely. Thus A_2 would count as a common cause of A_4 and A_5 if the above probabilistic relations were a definition of what it is to be a common cause. But by assumption A_2 is not a cause of A_5, and thus not a common cause of A_4 and A_5. Thus the probabilistic relations that are used to state Reichenbach's principle of the common cause should not be regarded as a definition of what a common cause is.

3. Q_k is an indirect cause of Q_p exactly when there is a chain of direct causes starting at Q_k and ending at Q_p. Q_p is an effect of Q_k iff Q_k is a cause of Q_p iff Q_k is a direct or indirect cause of Q_p.

4. Let me explain how this follows from the Markov condition using terminology and theorems from Spirtes, Glymour and Scheines 1993, chapter 3. Let us call a quantity Q_c a ‘forking path common cause’ of quantities Q_a and Q_b if and only if there exists a path that always goes causally downstream from Q_c to Q_a, a path that always goes causally downstream from Q_c to Q_b, and these paths do not have any vertices other than Q_c in common. Let us now conditionalize on all the forking path common causes of Q_a and Q_b. Claim: Every path from Q_a to Q_b will then be inactive. (Paths here are assumed not to contain any vertex more than once.) Let me indicate how to prove this claim.

If such a path P starts at Q_a going causally downstream, then it will at some point have to switch to going causally upstream, since Q_a is not a cause of Q_b. It will thus contain a collider. This collider will be inactive since we are not conditionalizing on it nor on any quantity that is a descendent of it, since we are conditionalizing only on quantities that are causally upstream from Q_a. (I am assuming that the graphs are not cyclical.) Thus such a path P will be inactive. Now consider any path P from Q_a to Q_b that starts at Q_a going causally upstream. There must be some point Q_c at which point P first starts going causally downstream (since Q_b is not a cause of Q_a). There are two possibilities: P keeps going causally downstream all the way until it reaches Q_b, or it reaches a collider Q_d where P switches back to going causally upstream again. In the first case, Q_c is a common cause of Q_a and Q_b. So we have conditionalized on it, so P is inactive. In the second case, Q_d is a collider. There are then 2 subcases: Q_d does not lie causally upstream from a forking path common cause of Q_a and Q_b, or it does. If Q_d does not lie causally upstream from a common cause, then it does not lie upstream from a quantity that is conditionalized upon, so the collider is inactive, so P is inactive. If Q_d does lie causally upstream from a forking path common cause of Q_a and Q_b, then there must be a downstream path P' from Q_d to Q_b. There are now 2 sub-subcases to consider.

Sub-subcase i: P' has no vertices in common with the part of path P that lies between Q_a and Q_c. In that case, Q_c is a forking path common cause of Q_a and Q_b: to go downstream from Q_c to Q_a, follow the part of P that lies between Q_c and Q_a;to go downstream from Q_c to Q_b (without intersecting the path to Q_a), first take the part of P that lies between Q_c and Q_d, and then follow P' to Q_b. So in this case we have conditionalized upon Q_c on P, so P is inactive.

Sub-subcase ii: every downstream path P' from Q_d to Q_b intersects somewhere with the part of P that lies between Q_a and Q_c. Take some such P', and consider the furthest point Q_e downstream along P' at which P' intersects with P between Q_a and Q_c. Such a Q_e must be a forking path common cause of Q_a and Q_b: follow P to get to Q_a, follow P' to get to Q_b. Thus we have conditionalized upon Q_e which lies on P. Thus P is inactive.

Thus any path P from Q_a to Q_b must be inactive once we have conditionalized upon all forking path common causes. Thus Q_a and Q_b are independent conditional upon a subset of all common causes of Q_a and Q_b.

5. The law of conditional independence is not violated by this type of case.

6. Let me sketch a proof. Any probability distribution that is allowed by the independence condition can be generated as follows. Assign some probability distribution over all the determinants outside S. By assumption this must be a probability distribution that is jointly independent, i.e. a product of

distributions for each such determinant. Now first look at the set S_1 of quantities in S that have no direct causes in S. The probability distribution over these quantities will be determined by the distribution of their determinants outside S, and hence be a jointly independent distribution. Now look at the set S_2 of quantities all of whose direct causes in S are in S_1. The probability distribution over any quantity S_2 is obtained by multiplying the probability distributions of its direct causes in S_1 with the probability distribution of its determinant outside S. (At least, this is so if all distinct values of direct causes of Q in S and determinants of Q outside S, determine distinct values of Q. This may not be so, but this does not affect the independence claims that I am making here.) And let us continue in this way with S_3, ... until we have a distribution over all quantities in S. The only correlations in the joint distribution over quantities in S that will now occur will be between causes and their effects, and between the effects of a common cause. For consider any quantities Q_1 and Q_2 that are not so related. They will have no ‘ultimate inputs’ (the determinants outside S that determine the values of these quantities) in common, so the sets of ‘ultimate inputs’ for Q_1 and ‘ultimate inputs’ for Q_2 are independent, which entails that Q_1 and Q_2 are themselves independent. Moreover, the correlations between any two quantities Q_1 and Q_2 that are not related as cause and effect will disappear when one conditionalizes upon the direct causes of one of them, say Q_1. For the only remaining input into Q_1 is independent of anything other than effects of Q_1. So Q_1 is independent of anything other than effects of Q_1 conditional upon the direct causes of Q_1. Hence, the causal Markov condition holds.

The Copenhagen Interpretation of Quantum Mechanics

As the theory of the atom, quantum mechanics is perhaps the most successful theory in the history of science. It enables physicists, chemists, and technicians to calculate and predict the outcome of a vast number of experiments and to create new and advanced technology based on the insight into the behavior of atomic objects. But it is also a theory that challenges our imagination. It seems to violate some fundamental principles of classical physics, principles that eventually have become a part of western common sense since the rise of the modern worldview in the Renaissance. So the aim of any metaphysical interpretation of quantum mechanics is to account for these violations.

The Copenhagen interpretation was the first general attempt to understand the world of atoms as this is represented by quantum mechanics. The founding father was mainly the Danish physicist Niels Bohr, but also Werner Heisenberg, Max Born and other physicists made important contributions to the overall understanding of the atomic world that is associated with the name of the capital of Denmark.

In fact Bohr and Heisenberg never totally agreed on how to understand the mathematical formalism of quantum mechanics, and none of them ever used the term “the Copenhagen interpretation” as a joint name for their ideas. In fact, Bohr once distanced himself from what he considered to be Heisenberg’s more subjective interpretation (*APHK*, p.51). The term is rather a label introduced by people opposing Bohr’s idea of complementarity, to identify what they saw as the common features behind the Bohr-Heisenberg interpretation as it emerged in the late 1920s. Today the Copenhagen interpretation is mostly regarded as synonymous with indeterminism, Bohr’s correspondence principle, Born’s statistical interpretation of the wave function, and Bohr’s complementarity interpretation of certain atomic phenomena.

1. The Background

In 1900 Max Planck discovered that the radiation spectrum of black bodies occurs only with discrete energies separated by the value hv where v is the frequency and h is a new constant, the so-called Planck constant. According to classical physics the intensity of this continuous radiation would grow unlimitedly with growing frequencies, resulting in what was called the ultraviolet catastrophe. But Planck's suggestion was that if black bodies only exchange energy with the radiation field in a proportion equal to hv that problem would disappear. The fact that the absorption and the emission of energy is discontinuous is in conflict with the principles of classical physics. A few years later Albert Einstein used this discovery in his explanation of the photoelectric effect. He suggested that light waves were quantized, and that the amount of energy which each quantum of light could deliver to the electrons of the cathode, was exactly hv. The next step came in 1911 when Ernest Rutherford performed some experiments shooting alpha particles into a gold foil. Based on these results he could set up a model of the atom in which the atom consisted of a heavy nucleus with a positive charge surrounded by negatively charged electrons like a small solar system. Also this model was in conflict with the laws of classical physics. According to classical mechanics and electrodynamics one might expect that the electrons orbiting around a positively charged nucleus would continuously emit radiation so that the nucleus would quickly swallow the electrons.

At this point Niels Bohr entered the scene and soon became the leading physicist on atoms. In 1913 Bohr, visiting Rutherford in Manchester, put forward a mathematical model of the atom which provided the first theoretical support for Rutherford's model and could explain the emission spectrum of the hydrogen atom (the Balmer series). The theory was based on two postulates:

1. An atomic system is only stable in a certain set of states, called stationary states, each state being associated with a discrete energy, and every change of energy corresponds to a complete transition from one state to another.
2. The possibility for the atom to absorb and emit radiation is determined by a law according to which the energy of the radiation is given by the energy difference between two stationary states being equal to hv.

Some features of Bohr's semi-classical model were indeed very strange compared to the principles of classical physics. It introduced an element of discontinuity and indeterminism foreign to classical mechanics:

1. Apparently not every point in space was accessible to an electron moving around a hydrogen nucleus. An electron moved in classical orbits, but during its transition from one orbit to another it was at no definite place between these orbits. Thus, an electron could only be in its ground state (the orbit of lowest energy) or an excited state (if an impact of another particle had forced it to leave its ground state.)

2. It was impossible to predict when the transition would take place and how it would take place. Moreover, there were no external (or internal) causes that determined the “jump” back again. Any excited electron might in principle move spontaneously to either a lower state or down to the ground state.
3. Rutherford pointed out that if, as Bohr did, one postulates that the frequency of light v, which an electron emits in a transition, depends on the difference between the initial energy level and the final energy level, it appears as if the electron must “know” to what final energy level it is heading in order to emit light with the right frequency.
4. Einstein made another strange observation. He was curious to know in which direction the photon decided to move off from the electron.

Between 1913 and 1925 Bohr, Arnold Sommerfeld and others were able to improve Bohr’s model, and together with the introduction of spin and Wolfgang Pauli’s exclusion principle it gave a reasonably good description of the basic chemical elements. The model ran into problems, nonetheless, when one tried to apply it to spectra other than that of hydrogen. So there was a general feeling among all leading physicists that Bohr’s model had to be replaced by a more radical theory. In 1925 Werner Heisenberg, at that time Bohr’s assistant in Copenhagen, laid down the basic principles of a complete quantum mechanics. In his new matrix theory he replaced classical commuting variables with non-commuting ones. The following year, Erwin Schrödinger gave a simpler formulation of the theory in which he introduced a second-order differential equation for a wave function. He himself attempted a largely classical interpretation of the wave function. However, already the same year Max Born proposed a consistent statistical interpretation in which the square of the absolute value of this wave function expresses a probability amplitude for the outcome of a measurement.

2. Classical Physics

Bohr saw quantum mechanics as a generalization of classical physics although it violates some of the basic ontological principles on which classical physics rests. These principles are:

- *The principle of space and time*, *i.e*., physical objects (systems) exist separately in space and time in such a way that they are localizable and countable, and physical processes (the evolution of systems) take place in space and time;
- *The principle of causality*, i.e., every event has a cause;
- *The principle of determination*, i.e., every later state of a system is uniquely determined by any earlier state;
- *The principle of continuity*, i.e., all processes exhibiting a difference between the initial and the final state have to go through every intervening state; and finally
- *The principle of the conservation of energy*, i.e., the energy of a closed system can be transformed into various forms but is never gained, lost or destroyed.

Due to these principles it is possible within, say, classical mechanics, to define a state of a system at any later time with respect to a state at any earlier time. So whenever we know the initial state consisting of

the system's position and momentum, and know all external forces acting on it, we also know what will be its later states. The knowledge of the initial state is usually acquired by observing the state properties of the system at the time selected as the initial moment. Furthermore, the observation of a system does not affect its later behavior or, if observation somehow should influence this behavior, it is always possible to incorporate the effect into the prediction of the system's later state. Thus, in classical physics we can always draw a sharp distinction between the state of the measuring instrument being used on a system and the state of the physical system itself. It means that the physical description of the system is objective because the definition of any later state is not dependent on measuring conditions or other observational conditions.

Much of Kant's philosophy can be seen as an attempt to provide satisfactory philosophical grounds for the objective basis of Newton's mechanics against Humean scepticism. Kant showed that classical mechanics is in accordance with the transcendental conditions for objective knowledge. Kant's philosophy undoubtedly influenced Bohr in various ways as many scholars in recent years have noticed (Hooker 1972; Folse 1985; Honnor 1987; Faye 1991; Kaiser 1992; and Chevalley 1994). Bohr was definitely neither a subjectivist nor a positivist philosopher, as Karl Popper (1967) and Mario Bunge (1967) have claimed. He explicitly rejected the idea that the experimental outcome is due to the observer. As he said: "It is certainly not possible for the observer to influence the events which may appear under the conditions he has arranged" (*APHK*, p.51). Not unlike Kant, Bohr thought that we could have objective knowledge only in case we can distinguish between the experiential subject and the experienced object. It is a precondition for the knowledge of a phenomenon as being something distinct from the sensorial subject, that we can refer to it as an object without involving the subject's experience of the object. In order to separate the object from the subject itself, the experiential subject must be able to distinguish between the form and the content of his or her experiences. This is possible only if the subject uses causal and spatial-temporal concepts for describing the sensorial content, placing phenomena in causal connection in space and time, since it is the causal space-time description of our perceptions that constitutes the criterion of reality for them. Bohr therefore believed that what gives us the possibility of talking about an object and an objectively existing reality is the application of those necessary concepts, and that the physical equivalents of "space," "time," "causation," and "continuity" were the concepts "position," "time," "momentum," and "energy," which he referred to as *the classical concepts*. He also believed that the above basic concepts exist already as preconditions of unambiguous and meaningful communication, built in as rules of our ordinary language. So, in Bohr's opinion the conditions for an objective description of nature given by the concepts of classical physics were merely a refinement of the preconditions of human knowledge.

3. The Correspondence Rule

The guiding principle behind Bohr's and later Heisenberg's work in the development of a consistent theory of atoms was the correspondence rule. Bohr had realized that according to his theory of the hydrogen atom, the frequencies of radiation due to the electron's transition between stationary states with large quantum numbers, i.e. states far from the ground state, coincide approximately with the results of classical electrodynamics. Hence in the search for a theory of quantum mechanics it became a

methodological requirement to Bohr that any further theory of the atom should predict values in domains of large quantum numbers that should be a close approximation to the values of classical physics. The correspondence rule was a heuristic principle meant to make sure that in areas where the influence of Planck's constant could be neglected the numerical values predicted by such a theory should be the same as if they were predicted by classical radiation theory.

The correspondence rule was an important methodological principle. In the beginning it had a clear technical meaning for Bohr. It is obvious, however, that it makes no sense to compare the numerical values of the theory of atoms with those of classical physics unless the meaning of the physical terms in both theories is commensurable. The correspondence rule was based on the metaphysical idea that classical concepts were indispensable for our understanding of physical reality, and it is only when classical phenomena and quantum phenomena are described in terms of the same classical concepts that we can compare different physical experiences. It was this broader sense of the correspondence rule that Bohr often had in mind later on.

Bohr's practical methodology stands therefore in direct opposition to Thomas Kuhn and Paul Feyerabend's historical view that succeeding theories, like classical mechanics and quantum mechanics, are incommensurable. In contrast to their philosophical claims of meaning gaps and partial lack of rationality in the choice between incommensurable theories, Bohr believed not just retrospectively that quantum mechanics was a natural generalization of classical physics, but he and Heisenberg followed in practice the requirements of the correspondence rule. Thus, in the mind of Bohr, the meaning of the classical concepts did not change but their application was restricted. This was the lesson of complementarity.

4. Complementarity

After Heisenberg had managed to formulate a consistent quantum mechanics in 1925, both he and Bohr began their struggle to find a coherent interpretation for the mathematical formalism. Heisenberg and Bohr followed somewhat different approaches. Where Heisenberg looked to the formalism and developed his famous uncertainty principle or indeterminacy relation, Bohr chose to analyze concrete experimental arrangements, especially the double-slit experiment. In a way Bohr merely regarded Heisenberg's relation as an expression of his general notion that our understanding of atomic phenomena builds on complementary descriptions. At Como in 1927 he presented for the first time his ideas according to which certain different descriptions are said to be complementary.

Bohr pointed to two sets of descriptions which he took to be complementary. On the one hand there are those that attribute either kinematic or dynamic properties to the atom, that is "space-time descriptions" are complementary to "claims of causality." On the other hand there are those that ascribe either wave or particle properties to a single object. How these two kinds of complementary sets of descriptions are related is something Bohr never indicated (Murdoch 1987). Even among people, like Rosenfeld and Pais, who claim they speak on behalf of Bohr, there is no agreement. The fact is that the description of light as either particles or waves was already a classical dilemma, which not even Einstein's definition of a

photon really solved since the momentum of the photon as a particle depends on the frequency of the light as a wave. Furthermore, Bohr eventually realized that the attribution of kinematic and dynamic properties to an object is complementary because the ascription of both of these conjugate variables rests on mutually exclusive experiments. The attribution of particle and wave properties to an object may, however, occur in a single experiment; for instance, in the double-slit experiment where the interference pattern consists of single dots. So within less than ten years after his Como lecture Bohr tacitly abandoned “wave-particle complementarity” in favor of the exclusivity of “kinematic-dynamic complementarity” (Held 1994).

It was clear to Bohr that any interpretation of the atomic world had to take into account an important empirical fact. The discovery of the quantization of action meant that quantum mechanics could not fulfill the above principles of classical physics. Every time we measure, say, an electron’s position the apparatus and the electron interact in an uncontrollable way, so that we are unable to measure the electron's momentum at the same time. Until the mid-1930s when Einstein, Podolsky and Rosen published their famous thought-experiment with the intention of showing that quantum mechanics was incomplete, Bohr spoke as if the measurement apparatus disturbed the electron. This paper had a significant influence on Bohr’s line of thought. Apparently, Bohr realized that speaking of disturbance seemed to indicate—as some of his opponents may have understood him—that atomic objects were classical particles with definite inherent kinematic and dynamic properties. After the EPR paper he stated quite clearly: “the whole situation in atomic physics deprives of all meaning such inherent attributes as the idealization of classical physics would ascribe to such objects.”

Also after the EPR paper Bohr spoke about Heisenberg’s “indeterminacy relation” as indicating the ontological consequences of his claim that kinematic and dynamic variables are ill-defined unless they refer to an experimental outcome. Earlier he had often called it Heisenberg’s “uncertainty relation”, as if it were a question of a merely epistemological limitation. Furthermore, Bohr no longer mentioned descriptions as being complementary, but rather phenomena or information. He introduced the definition of a “phenomenon” as requiring a complete description of the entire experimental arrangement, and he took a phenomenon to be a measurement of the values of either kinematic or dynamic properties.

Bohr’s more mature view, i.e., his view after the EPR paper, on complementarity and the interpretation of quantum mechanics may be summarized in the following points:

1. The interpretation of a physical theory has to rely on an experimental practice.
2. The experimental practice presupposes a certain pre-scientific practice of description, which establishes the norm for experimental measurement apparatus, and consequently what counts as scientific experience.
3. Our pre-scientific practice of understanding our environment is an adaptation to the sense experience of separation, orientation, identification and reidentification over time of physical objects.
4. This pre-scientific experience is grasped in terms of common categories like thing’s position and change of position, duration and change of duration, and the relation of cause and effect, terms and principles that are now parts of our common language.

5. These common categories yield the preconditions for objective knowledge, and any description of nature has to use these concepts to be objective.
6. The concepts of classical physics are merely exact specifications of the above categories.
7. The classical concepts—and not classical physics itself—are therefore necessary in any description of physical experience in order to understand what we are doing and to be able to communicate our results to others, in particular in the description of quantum phenomena as they present themselves in experiments;
8. Planck's empirical discovery of the quantization of action requires a revision of the foundation for the use of classical concepts, because they are not all applicable at the same time. Their use is well defined only if they apply to experimental interactions in which the quantization of action can be regarded as negligible.
9. In experimental cases where the quantization of action plays a significant role, the application of a classical concept does not refer to independent properties of the object; rather the ascription of either kinematic or dynamic properties to the object as it exists independently of a specific experimental interaction is ill-defined.
10. The quantization of action demands a limitation of the use of classical concepts so that these concepts apply only to a phenomenon, which Bohr understood as the macroscopic manifestation of a measurement on the object, i.e. the uncontrollable interaction between the object and the apparatus.
11. The quantum mechanical description of the object differs from the classical description of the measuring apparatus, and this requires that the object and the measuring device should be separated in the description, but the line of separation is not the one between macroscopic instruments and microscopic objects. It has been argued in detail (Howard 1994) that Bohr pointed out that parts of the measuring device may sometimes be treated as parts of the object in the quantum mechanical description.
12. The quantum mechanical formalism does not provide physicists with a 'pictorial' representation: the ψ-function does not, as Schrödinger had hoped, represent a new kind of reality. Instead, as Born suggested, the square of the absolute value of the ψ-function expresses a probability amplitude for the outcome of a measurement. Due to the fact that the wave equation involves an imaginary quantity this equation can have only a symbolic character, but the formalism may be used to predict the outcome of a measurement that establishes the conditions under which concepts like position, momentum, time and energy apply to the phenomena.
13. The ascription of these classical concepts to the phenomena of measurements rely on the experimental context of the phenomena, so that the entire setup provides us with the defining conditions for the application of kinematic and dynamic concepts in the domain of quantum physics.
14. Such phenomena are complementary in the sense that their manifestations depend on mutually exclusive measurements, but that the information gained through these various experiments exhausts all possible objective knowledge of the object.

Earlier generations of philosophers have often accused the Copenhagen interpretation of being subjectivistic or positivistic. Today anyone who has studied Bohr's essays carefully agrees that his view is neither. There are, as many have noticed, both typically realist as well as antirealist elements involved

in it, and it has affinities to Kant or neo-Kantianism.

Bohr thought of the atom as real. Atoms are neither heuristic nor logical constructions. A couple of times he emphasized this directly using arguments from experiments in a very similar way to Ian Hacking and Nancy Cartwright much later. What he did not believe was that the quantum mechanical formalism was true in the sense that it gave us a literal ('pictorial') rather than a symbolic representation of the quantum world. It makes much sense to characterize Bohr in modern terms as an entity realist who opposes theory realism (Folse 1987). It is because of the imaginary quantities in quantum mechanics (where the commutation rule for canonically conjugate variable, p and q, introduces Planck's constant into the formalism by $pq - qp = ih/2\pi$) that quantum mechanics does not give us a 'pictorial' representation of the world. Neither does the theory of relativity, Bohr argued, provide us with a literal representation, since the velocity of light is introduced with a factor of i in the definition of the fourth coordinate in a four-dimensional manifold (*CC*, p. 86 and p. 105). Instead these theories can only be used symbolically to predict observations under well-defined conditions. Thus Bohr was an antirealist or an instrumentalist when it comes to theories.

In general, Bohr considered the demands of complementarity in quantum mechanics to be logically on a par with the requirements of relativity in the theory of relativity. He believed that both theories were a result of novel aspects of the observation problem, namely the fact that observation in physics is context-dependent. This again is due to the existence of a maximum velocity of propagation of all actions in the domain of relativity and a minimum of any action in the domain of quantum mechanics. And it is because of these universal limits that it is impossible in the theory of relativity to make an unambiguous separation between time and space without reference to the observer (the context) and impossible in quantum mechanics to make a sharp distinction between the behavior of the object and its interaction with the means of observation (*CC*, p. 105).

In emphasizing the necessity of classical concepts for the description of the quantum phenomena, Bohr was influenced by Kant or neo-Kantianism. But he was a naturalized or a pragmatized Kantian. The classical concepts are merely explications of common concepts that are already a result of our adaptation to the world. These concepts and the conditions of their application determine the conditions for objective knowledge. The discovery of the quantization of action has revealed to us, however, that we cannot apply these concepts to quantum objects as we did in classical physics. Now kinematic and dynamic properties (represented by conjugate variables) can be meaningfully ascribed to the object only in relation to some actual experimental results, whereas classical physics attributes such properties to the object regardless of whether we actually observe them or not. In other words, Bohr denied that classical concepts could be used to attribute properties to a physical world in-itself behind the phenomena, i.e. properties different from those being observed. In contrast, classical physics rests on an idealization, he said, in the sense that it assumes that the physical world has these properties in-itself, i.e. as inherent properties, independent of their actual observation.

The Copenhagen interpretation is first and foremost a semantic and epistemological reading of quantum mechanics that carries certain ontological implications. Bohr's view was, to phrase it in a modern

philosophical jargon, that the truth conditions of sentences ascribing a certain kinematic or dynamic value to an atomic object are dependent on the apparatus involved, in such a way that these truth conditions have to include reference to the experimental setup as well as the actual outcome of the experiment. Hence, those physicists who accuse this interpretation of operating with a mysterious collapse of the wave function during measurements do not understand a word of it. Bohr accepted the Born statistical interpretation because he believed that the ψ-function has only a symbolic meaning and does not represent anything real. It makes sense to talk about a collapse of the wave function only if, as Bohr put it, the ψ-function can be given a pictorial representation, something he strongly denied.

Indeed, Bohr, Heisenberg and many other physicists considered the Copenhagen Interpretation to be the only rational interpretation of the quantum world. They thought that it gave us the understanding of atomic phenomena that is in accordance with the conditions for any physical description and the possible objective knowledge of the world. Bohr believed that atoms are real, but it remains a much debated point in the recent literature what sort of reality he believed them to have, whether or not they are something beyond and different from what they are observed to be (Folse 1985 and 1994; and Faye 1991).

The Uncertainty Principle

Quantum mechanics is generally regarded as the physical theory which is our best candidate yet for a universal and fundamental description of the physical world. The conceptual framework employed by this theory differs drastically from that of classical physics. Indeed, the transition from classical to quantum physics marks a genuine revolution in our understanding of the physical world.

One striking aspect of the difference between classical and quantum physics is that whereas classical mechanics presupposes that one can assign exact simultaneous values to the position and momentum of a particle, quantum mechanics denies this possibility. Instead, according to quantum mechanics, the more precisely the position of a particle is given, the less precisely one can say what its momentum is. This is (a simplistic and preliminary formulation of) the quantum mechanical uncertainty principle. This principle played an important role in many discussions on the philosophical implications of quantum mechanics and on the consistency of the interpretation endorsed by the founding fathers Heisenberg and Bohr, the so-called Copenhagen interpretation.

This, of course, should not suggest that the uncertainty principle is the only aspect in which classical and quantum physics differ conceptually. In particular the implications of quantum mechanics for notions such as (non)-locality, entanglement and identity play no less havoc with classical intuitions.

1. Introduction

The uncertainty principle is certainly one of the most famous and important aspects of quantum mechanics. Often, it has even been regarded as the most distinctive feature in which this theory differs from a classical conception of the physical world. Roughly speaking, the uncertainty principle states that one cannot assign exact simultaneous values to the position and momentum of a quantum mechanical system. Rather, we can only determine such quantities with some characteristic ‘uncertainties’, which cannot both become arbitrarily small at the same time. But what exactly is the meaning of this uncertainty principle? And indeed, is it really a principle of quantum mechanics? In particular, what does it mean that a quantity is determined only up to some uncertainty? These are the main questions we will explore in the following, focussing on the views of Heisenberg and Bohr.

In many expositions of the subject, the ‘uncertainty’ may refer sometimes to a lack of knowledge of a quantity by an observer, or to the experimental inaccuracy with which a quantity is measured, or to some ambiguity in the definition of a quantity, or to a statistical spread in some ensemble of similarly prepared systems. Corresponding to this confusing multitude of different meanings, there are many different names for these ‘uncertainties’. For example, apart from those already mentioned (inaccuracy, spread) one finds imprecision, indefiniteness, indeterminateness, indeterminacy, latitude, etc. As we shall see in the sequel, even Heisenberg and Bohr did not decide on a single terminology. Forestalling a discussion about which name is the most appropriate, we mention here that we use the name ‘uncertainty principle’ simply because it seems the most common one in the literature.

2. Heisenberg

2.1 Heisenberg's road to the uncertainty relations

Heisenberg introduced his now famous relations in an article of 1927, entitled "*Ueber den anschaulichen Inhalt der quantentheoretischen Kinematik und Mechanik*". A (partial) translation of this title is: "On the *anschaulich* content of quantum theoretical kinematics and mechanics". Here, the term *anschaulich* is particularly notable. Apparently, it is one of those German words that defy an unambiguous translation into other languages. Heisenberg's title is translated as "*On the physical content* …" by Wheeler and Zurek (1983). His collected works (Heisenberg, 1984) translate it as "*On the perceptible content* …", while Cassidy's biography of Heisenberg (Cassidy, 1992), refers to the paper as "*On the perceptual content* …". Literally, the closest translation of the term *anschaulich* is ‘visualizable’. But, as in most languages, words that make reference to vision are not always intended literally. Seeing is widely used as a metaphor for understanding, especially for immediate understanding. Hence, *anschaulich* also means ‘intelligible’ or ‘intuitive’.[1]

Why was this issue of the *Anschaulichkeit* of quantum mechanics such a prominent concern to Heisenberg? This question has already been considered by a number of commentators (Jammer, 1977; Miller 1982; de Regt, 1997; Beller, 1999). For the answer, it turns out, we must go back a little in time. In 1925 Heisenberg had developed the first coherent mathematical formalism for quantum theory (Heisenberg, 1925). His leading idea was that only those quantities that are in principle observable should play a role in the theory, and that all attempts to form a picture of what goes on inside the atom should be avoided. In atomic physics the observational data were obtained from spectroscopy and associated with atomic transitions. Thus, Heisenberg was led to consider the 'transition quantities' as the basic ingredients of the theory. Max Born, later that year, realized that the transition quantities obeyed the rules of matrix calculus, a branch of mathematics that was not so well-known then as it is now. In a famous series of papers Heisenberg, Born and Jordan developed this idea into the matrix mechanics version of quantum theory.

Formally, matrix mechanics remains close to classical mechanics. The central idea is that all physical quantities must be represented by infinite self-adjoint matrices (later identified with operators on a Hilbert space). It is postulated that the matrices $\boldsymbol{q}$ and $\boldsymbol{p}$ representing the canonical position and momentum variables of a particle satisfy the so-called canonical commutation rule

$$\boldsymbol{qp} - \boldsymbol{pq} = i\hbar \qquad (1)$$

where $\hbar = h/2\pi$, h denotes Planck's constant, and boldface type is used to represent matrices. The new theory scored spectacular empirical success by encompassing nearly all spectroscopic data known at the time, especially after the concept of the electron spin was included in the theoretical framework.

It came as a great surprise, therefore, when one year later, Erwin Schrödinger presented an alternative theory, which became known as wave mechanics. Schrödinger assumed that an electron could be represented as an oscillating charge cloud, evolving continuously in space and time according to a wave equation. The discrete frequencies in the atomic spectra were not due to discontinuous transitions (quantum jumps) but to a resonance phenomenon. Further, Schrödinger argued that the two theories were equivalent.[2]

Even so, the two approaches differed greatly in interpretation and spirit. Whereas Heisenberg eschewed the use of visualizable pictures, and accepted discontinuous transitions as a primitive notion, Schrödinger claimed as an advantage of his theory that it was *anschaulich*. In Schrödinger's vocabulary, this meant that the theory represented the observational data by means of continuously evolving causal processes in space and time. He considered this condition of *Anschaulichkeit* to be an essential requirement on any acceptable physical theory. In fact, Schrödinger was not alone in appreciating this aspect of his theory. Many other leading physicists were attracted to wave mechanics for the same reason. For a while in 1926, before it emerged that wave mechanics has serious problems of its own, Schrödinger's approach seemed to gather more support in the physics community than matrix mechanics.

Understandably, Heisenberg was unhappy about this development. In a letter of 8 June 1926 to Pauli he

confessed that Schrödinger's approach disgusted him, and in particular: "What Schrödinger writes about the *Anschaulichkeit* of his theory, … I consider *Mist* (Pauli, 1979, p. 328)". Again, this last German term is translated differently by various commentators: as "junk" (Miller, 1982) "rubbish" (Beller 1999) "crap" (Cassidy, 1992), and perhaps more literally, as "bullshit" (de Regt, 1997). Nevertheless, in published writings, Heisenberg voiced a more balanced opinion. In a paper in *Die Naturwissenschaften* (1926) he summarized the peculiar situation which the simultaneous development of two competing theories had brought about. Although he argued that Schrödinger's interpretation was untenable, he admitted that matrix mechanics did not provide the *Anschaulichkeit* which made wave mechanics so attractive. He concluded: "to obtain a contradiction-free *anschaulich* interpretation, we still lack some essential feature in our image of the structure of matter". The purpose of his 1927 paper was to provide exactly this lacking feature.

2.2 Heisenberg's argument

Let us now look at the argument that led Heisenberg to his uncertainty relations. He started by redefining the notion of *Anschaulichkeit*. Whereas Schrödinger associated this term with the provision of a causal space-time picture of the phenomena, Heisenberg, by contrast, declared:

> We believe we have gained *anschaulich* understanding of a physical theory, if in all simple cases, we can grasp the experimental consequences qualitatively and see that the theory does not lead to any contradictions. Heisenberg, 1927, p. 172)

His goal was, of course, to show that, in this new sense of the word, matrix mechanics could lay the same claim to *Anschaulichkeit* as wave mechanics.

To do this, he adopted an operational assumption: terms like ‘the position of a particle’ have meaning only if one specifies a suitable experiment by which ‘the position of a particle’ can be measured. We will call this assumption the ‘measurement=meaning principle’. In general, there is no lack of such experiments, even in the domain of atomic physics. However, experiments are never completely accurate. We should be prepared to accept, therefore, that in general the meaning of these quantities is also determined only up to some characteristic inaccuracy.

As an example, he considered the measurement of the position of an electron by a microscope. The accuracy of such a measurement is limited by the wave length of the light illuminating the electron. Thus, it is possible, in principle, to make such a position measurement as accurate as one wishes, but only by using light of a very short wave length, e.g., γ-rays. But for γ-rays, the Compton effect cannot be ignored: the interaction of the electron and the illuminating light should then be considered as a collision of at least one photon with the electron. In such a collision, the electron suffers a recoil which disturbs its momentum. Moreover, the shorter the wave length, the larger is this change in momentum. Thus, at the moment when the position of the particle is accurately known, Heisenberg argued, its momentum cannot be accurately known:

> At the instant of time when the position is determined, that is, at the instant when the photon is scattered by the electron, the electron undergoes a discontinuous change in momentum. This change is the greater the smaller the wavelength of the light employed, i.e., the more exact the determination of the position. At the instant at which the position of the electron is known, its momentum therefore can be known only up to magnitudes which correspond to that discontinuous change; thus, the more precisely the position is determined, the less precisely the momentum is known, and conversely (Heisenberg, 1927, p. 174-5).

This is the first formulation of the uncertainty principle. In its present form it is an epistemological principle, since it limits what we can *know* about the electron. From "elementary formulae of the Compton effect" Heisenberg estimated the ‘imprecisions’ to be of the order

$$\delta p \delta q \sim h \qquad (2)$$

He continued: "In this circumstance we see the direct *anschaulich* content of the relation $\boldsymbol{qp} - \boldsymbol{pq} = i\hbar$".

He went on to consider other experiments, designed to measure other physical quantities and obtained analogous relations for time and energy:

$$\delta t \delta E \sim h \qquad (3)$$

and action J and angle w

$$\delta w \delta J \sim h \qquad (4)$$

which he saw as corresponding to the "well-known" relations

$$\boldsymbol{tE} - \boldsymbol{Et} = i\hbar \quad \text{or} \quad \boldsymbol{wJ} - \boldsymbol{Jw} = i\hbar \qquad (5)$$

However, we shall see in Section 2.5 that these generalisations did not turn out as straightforward as Heisenberg suggested.

He summarized his findings in a general conclusion: all concepts used in classical mechanics are also well-defined in the realm of atomic processes. But, as a pure fact of experience ("*rein erfahrungsgemäß*"), experiments that serve to provide such a definition for one quantity are subject to particular indeterminacies, obeying relations (2)-(4) which prohibit them from providing a simultaneous definition of two canonically conjugate quantities. Note that in this formulation the emphasis has slightly shifted: he now speaks of a limit on the definition of concepts, i.e. not merely on what we can *know*, but what we can meaningfully *say* about a particle. Of course, this stronger formulation follows by

application of the above measurement=meaning principle: if there are, as Heisenberg claims, no experiments that allow a simultaneous precise measurement of two conjugate quantities, then these quantities are also not simultaneously well-defined.

Heisenberg's paper has an interesting "Addition in proof" mentioning critical remarks by Bohr, who saw the paper only after it had been sent to the publisher. Among other things, Bohr pointed out that in the microscope experiment it is not the change of the momentum of the electron that is important, but rather the circumstance that this change cannot be precisely determined in the *same* experiment. An improved version of the argument, which responds to this objection, is given in Heisenberg's Chicago lectures of 1930.

Here (Heisenberg, 1930, p. 16), it is assumed that the electron is illuminated by light of wavelength λ and that the scattered light enters a microscope with aperture angle ε. According to the laws of classical optics, the accuracy of the microscope depends on both the wave length and the aperture angle; Abbe's criterium for its ‘resolving power’, i.e. the size of the smallest discernable details, gives

$$\delta q \sim \lambda/\sin\varepsilon \qquad (6)$$

On the other hand, the direction of a scattered photon, when it enters the microscope, is unknown within the angle ε, rendering the momentum change of the electron uncertain by an amount

$$\delta p \sim h \sin\varepsilon/\lambda \qquad (7)$$

leading again to the result (2).

Let us now analyse Heisenberg's argument in more detail. First note that, even in this improved version, Heisenberg's argument is incomplete. According to Heisenberg's ‘measurement=meaning principle’, one must also specify, in the given context, what the meaning is of the phrase ‘momentum of the electron’, in order to make sense of the claim that this momentum is changed by the position measurement. A solution to this problem can again be found in the Chicago lectures (Heisenberg, 1930, p. 15). Here, he assumes that initially the momentum of the electron is precisely known, e.g. it has been measured in a previous experiment with an inaccuracy δp_i, which may be arbitrarily small. Then, its position is measured with inaccuracy δq, and after this, its final momentum is measured with an inaccuracy δp_f. All three measurements can be performed with arbitrary precision. Thus, the three quantities δp_i, δq, and δp_f can be made as small as one wishes. If we assume further that the initial momentum has not changed until the position measurement, we can speak of a definite momentum until the time of the position measurement. Moreover we can give operational meaning to the idea that the momentum is changed during the position measurement: the outcome of the second momentum measurement (say p_f) will generally differ from the initial value p_i. In fact, one can also show that this change is discontinuous, by varying the time between the three measurements.

Let us now try to see, adopting this more elaborate set-up, if we can complete Heisenberg's argument. We have now been able to give empirical meaning to the ‘change of momentum’ of the electron, $p_f - p_i$. Heisenberg's argument claims that the order of magnitude of this change is at least inversely proportional to the inaccuracy of the position measurement:

$$|p_f - p_i| \delta q \sim h \quad (8)$$

However, can we now draw the conclusion that the momentum is only imprecisely defined? Certainly not. Before the position measurement, its value was p_i, after the measurement it is p_f. One might, perhaps, claim that the value at the very instant of the position measurement is not yet defined, but we could simply settle this assignment by a convention (e.g., we might assign the mean value $(p_i + p_f)/2$ to this instant). But then, the momentum is precisely determined at all instants, and Heisenberg's formulation of the uncertainty principle no longer follows. The above attempt of completing Heisenberg's argument thus overshoots its mark.

A solution to this problem can again be found in the Chicago Lectures. Heisenberg admits that position and momentum can be known exactly. He writes:

> If the velocity of the electron is at first known, and the position then exactly measured, the position of the electron for times previous to the position measurement may be calculated. For these past times, $\delta p \delta q$ is smaller than the usual bound. (Heisenberg 1930, p. 15)

Indeed, Heisenberg says: "the uncertainty relation does not hold for the past".

Apparently, when Heisenberg refers to the uncertainty or imprecision of a quantity, he means that the value of this quantity cannot be given *beforehand*. In the sequence of measurements we have considered above, the uncertainty in the momentum after the measurement of position has occurred, refers to the idea that the value in momentum is not fixed *before* the final momentum measurement takes place. Once this measurement is performed, and reveals a value p_f, the uncertainty relation no longer holds; these values then belong to the past. Clearly, then, Heisenberg is concerned with *unpredictability*: the point is not that the momentum of a particle changes, due to a position measurement, but rather that it changes by an unpredictable amount. It is, however always possible to measure, and hence define, the size of this change in a subsequent measurement of the final momentum with arbitrary precision.

Although Heisenberg admits that we can consistently attribute values of momentum and position to an electron in the past, he sees little merit in such talk. He points out that these values can never be used as initial conditions in a prediction about the future behavior of the electron, or subjected to experimental verification. Whether or not we grant them physical reality is, as he puts it, a matter of personal taste. Heisenberg's own taste is, of course, to deny their physical reality. For example, he writes, "I believe that one can formulate the emergence of the classical ‘path’ of a particle pregnantly as follows: *the ‘path’ comes into being only because we observe it*" (Heisenberg, 1927, p. 185). Apparently, in his view, a

measurement does not only serve to give meaning to a quantity, it *creates* a particular value for this quantity. This may be called the ‘measurement=creation’ principle. It is an ontological principle, for it states what is physically real.

This then leads to the following picture. First we measure the momentum of the electron very accurately. By ‘measurement= meaning’, this entails that the term "the momentum of the particle" is now well-defined. Moreover, by the ‘measurement=creation’ principle, we may say that this momentum is physically real. Next, the position is measured with inaccuracy δq. At this instant, the position of the particle becomes well-defined and, again, one can regard this as a physically real attribute of the particle. However, the momentum has now changed by an amount, which is unpredictable by an order of magnitude $| p_f - p_i | \sim h/\delta q$. The meaning and validity of this claim can be verified by a subsequent momentum measurement.

The question is then what status we shall assign to the momentum of the electron just before its final measurement. Is it real? According to Heisenberg it is not. Before the final measurement, the best we can attribute to the electron is some unsharp, or fuzzy momentum. These terms are meant here in an ontological sense, characterizing a real attribute of the electron.

2.3 The interpretation of Heisenberg's relation

The relations Heisenberg had proposed were soon considered to be a cornerstone of the Copenhagen interpretation of quantum mechanics. Just a few months later, Kennard (1927) already called them the "essential core" of the new theory. Taken together with Heisenberg's contention that they provided the intuitive content of the theory and their prominent role in later discussions on the Copenhagen interpretation, a dominant view emerged in which they were regarded as a fundamental principle of the theory.

The interpretation of these relations has often been debated. Do Heisenberg's relations express restrictions on the experiments we can perform on quantum systems, and, therefore, restrictions on the information we can gather about such systems; or do they express restrictions on the meaning of the concepts we use to describe quantum systems? Or else, are they restrictions of an ontological nature, i.e., do they assert that a quantum system simply does not possess a definite value for its position and momentum at the same time? The difference between these interpretations is partly reflected in the various names by which the relations are known, e.g. as ‘inaccuracy relations’, or: ‘uncertainty’, ‘indeterminacy’ or ‘unsharpness relations’, etc. The debate between these different views has been addressed by many authors, but it has never been settled completely. Let it suffice here to make only two general observations.

First, it is clear that in Heisenberg's own view, all the above questions stand or fall together. Indeed, we have seen that he adopted an operational "measurement=meaning" principle according to which the meaningfulness of a physical quantity was equivalent to the existence of an experiment purporting to measure that quantity. Similarly, his "measurement=creation" principle allowed him to attribute physical reality to such quantities. Hence, Heisenberg's discussions moved rather freely and quickly from talk

about experimental inaccuracies to epistemological or ontological issues and back again.

However, ontological questions seemed to be of somewhat less interest to him. For example, there is a passage (Heisenberg, 1927, p. 197), where he discusses the idea that, behind our observational data, there might still exist a hidden reality in which quantum systems have definite values for position and momentum, unaffected by the uncertainty relations. He emphatically dismisses this conception as an unfruitful and meaningless speculation, because, as he says, the aim of physics is only to describe observable data. Similarly in the Chicago Lectures (Heisenberg 1930, p. 11) he warns against the fact that the human language permits the utterance of statements which have no empirical content at all, but nevertheless produce a picture in our imagination. He notes, "One should be especially careful in using the words 'reality', 'actually', etc., since these words very often lead to statements of the type just mentioned." So, Heisenberg also endorsed an interpretation of his relations as rejecting a reality in which particles have simultaneous definite values for position and momentum.

The second observation is that although for Heisenberg experimental, informational, epistemological and ontological formulations of his relations were, so to say, just different sides of the same coin, this does not hold for those who do not share his operational principles or his view on the task of physics. Alternative points of view, in which e.g. the ontological reading of the uncertainty relations is denied, are therefore still viable. The statement, often found in the literature of the thirties, that Heisenberg had *proved* the impossibility of associating a definite position and momentum to a particle is certainly wrong. But the precise meaning one can coherently attach to Heisenberg's relations depends rather heavily on the interpretation one favors for quantum mechanics as a whole. And in view of the fact that no agreement has been reached on this latter issue, one cannot expect agreement on the meaning of the uncertainty relations either.

2.4 Uncertainty relations or uncertainty principle?

Let us now move to another question about Heisenberg's relations: do they express a *principle* of quantum theory? Probably the first influential author to call these relations a 'principle' was Eddington, who, in his Gifford Lectures of 1928 referred to them as the 'Principle of Indeterminacy'. In the English literature the name uncertainty principle became most common. It is used both by Condon and Robertson in 1929, and also in the English version of Heisenberg's Chicago Lectures (Heisenberg, 1930), although, remarkably, nowhere in the original German version of the same book (see also Cassidy, 1998). Indeed, Heisenberg never seems to have endorsed the name 'principle' for his relations. His favourite terminology was 'inaccuracy relations' (*Ungenauigkeitsrelationen*) or 'indeterminacy relations' (*Unbestimmtheitsrelationen*). We know only one passage, in Heisenberg's own Gifford lectures, delivered in 1955-56 (Heisenberg, 1958, p. 43), where he mentioned that his relations "are usually called relations of uncertainty or principle of indeterminacy". But this can well be read as his yielding to common practice rather than his own preference.

But does the relation (2) qualify as a principle of quantum mechanics? Several authors, foremost Karl Popper (1967), have contested this view. Popper argued that the uncertainty relations cannot be granted

the status of a principle, on the grounds that they are derivable from the theory, whereas one cannot obtain the theory from the uncertainty relations. (The argument being that one can never derive any equation, say, the Schrödinger equation, or the commutation relation (1), from an inequality.)

Popper's argument is, of course, correct but we think it misses the point. There are many statements in physical theories which are called principles even though they are in fact derivable from other statements in the theory in question. A more appropriate departing point for this issue is not the question of logical priority but rather Einstein's distinction between ‘constructive theories’ and ‘principle theories’.

Einstein proposed this famous classification in (Einstein, 1919). Constructive theories are theories which postulate the existence of simple entities behind the phenomena. They endeavour to reconstruct the phenomena by framing hypotheses about these entities. Principle theories, on the other hand, start from empirical principles, i.e. general statements of empirical regularities, employing no or only a bare minimum of theoretical terms. The purpose is to build up the theory from such principles. That is, one aims to show how these empirical principles provide sufficient conditions for the introduction of further theoretical concepts and structure.

The prime example of a theory of principle is thermodynamics. Here the role of the empirical principles is played by the statements of the impossibility of various kinds of perpetual motion machines. These are regarded as expressions of brute empirical fact, providing the appropriate conditions for the introduction of the concepts of energy and entropy and their properties. (There is a lot to be said about the tenability of this view, but that is not the topic of this entry.)

Now obviously, once the formal thermodynamic theory is built, one can also *derive* the impossibility of the various kinds of perpetual motion. (They would violate the laws of energy conservation and entropy increase.) But this derivation should not misguide one into thinking that they were no principles of the theory after all. The point is just that empirical principles are statements that do not rely on the theoretical concepts (in this case entropy and energy) for their meaning. They are interpretable independently of these concepts and, further, their validity on the empirical level still provides the physical content of the theory.

A similar example is provided by special relativity, another theory of principle, which Einstein deliberately designed after the ideal of thermodynamics. Here, the empirical principles are the light postulate and the relativity principle. Again, once we have built up the modern theoretical formalism of the theory (the Minkowski space-time) it is straightforward to prove the validity of these principles. But again this does not count as an argument for claiming that they were no principles after all. So the question whether the term ‘principle’ is justified for Heisenberg's relations, should, in our view, be understood as the question whether they are conceived of as empirical principles.

One can easily show that this idea was never far from Heisenberg's intentions. We have already seen that Heisenberg presented them as the result of a "pure fact of experience". A few months after his 1927 paper, he wrote a popular paper with the title "*Ueber die Grundprincipien der Quantenmechanik*" ("On the fundamental principles of quantum mechanics") where he made the point even more clearly. Here

Heisenberg described his recent break-through in the interpretation of the theory as follows: "It seems to be a general law of nature that we cannot determine position and velocity simultaneously with arbitrary accuracy". Now actually, and in spite of its title, the paper does not identify or discuss any ‘fundamental principle’ of quantum mechanics. So, it must have seemed obvious to his readers that he intended to claim that the uncertainty relation was a fundamental principle, forced upon us as an empirical law of nature, rather than a result derived from the formalism of this theory.

This reading of Heisenberg's intentions is corroborated by the fact that, even in his 1927 paper, applications of his relation frequently present the conclusion as a matter of principle. For example, he says "In a stationary state of an atom its phase is *in principle* indeterminate" (Heisenberg, 1927, p. 177, [emphasis added]). Similarly, in a paper of 1928, he described the content of his relations as: "It has turned out that it is *in principle* impossible to know, to measure the position and velocity of a piece of matter with arbitrary accuracy. (Heisenberg, 1984, p. 26, [emphasis added])"

So, although Heisenberg did not originate the tradition of calling his relations a principle, it is not implausible to attribute the view to him that the uncertainty relations represent an empirical principle that could serve as a foundation of quantum mechanics. In fact, his 1927 paper expressed this desire explicitly: "Surely, one would like to be able to deduce the quantitative laws of quantum mechanics directly from their *anschaulich* foundations, that is, essentially, relation [(2)]" (*ibid*, p. 196). This is not to say that Heisenberg was successful in reaching this goal, or that he did not express other opinions on other occasions.

Let us conclude this section with three remarks. First, if the uncertainty relation is to serve as an empirical principle, one might well ask what its direct empirical support is. In Heisenberg's analysis, no such support is mentioned. His arguments concerned thought experiments in which the validity of the theory, at least at a rudimentary level, is implicitly taken for granted. Jammer (1974, p. 82) conducted a literature search for high precision experiments that could seriously test the uncertainty relations and concluded they were still scarce in 1974. Real experimental support for the uncertainty relations in experiments in which the inaccuracies are close to the quantum limit have come about only more recently. (See Kaiser, Werner and George 1983, Uffink 1985, Nairz, Andt, and Zeilinger, 2001.)

A second point is the question whether the theoretical structure or the quantitative laws of quantum theory can indeed be derived on the basis of the uncertainty principle, as Heisenberg wished. Serious attempts to build up quantum theory as a full-fledged Theory of Principle on the basis of the uncertainty principle have never been carried out. Indeed, the most Heisenberg could and did claim in this respect was that the uncertainty relations created "room" (Heisenberg 1927, p. 180) or "freedom" (Heisenberg, 1931, p. 43) for the introduction of some non-classical mode of description of experimental data, not that they uniquely lead to the formalism of quantum mechanics. A serious proposal to construe quantum mechanics as a theory of principle was provided only recently by Bub (2000). But, remarkably, this proposal does not use the uncertainty relation as one of its fundamental principles.

Third, it is remarkable that in his later years Heisenberg put a somewhat different gloss on his relations.

In his autobiography *Der Teil und das Ganze* of 1969 he described how he had found his relations inspired by a remark by Einstein that "it is the theory which decides what one can observe" -- thus giving precedence to theory above experience, rather than the other way around. Some years later he even admitted that his famous discussions of thought experiments were actually trivial since "… if the process of observation itself is subject to the laws of quantum theory, it must be possible to represent its result in the mathematical scheme of this theory" (Heisenberg, 1975, p. 6).

2.5 Mathematical elaboration

When Heisenberg introduced his relation, his argument was based only on qualitative examples. He did not provide a general, exact derivation of his relations.[3] Indeed, he did not even give a definition of the uncertainties δq, etc., occurring in these relations. Of course, this was consistent with the announced goal of that paper, i.e. to provide some qualitative understanding of quantum mechanics for simple experiments.

The first mathematically exact formulation of the uncertainty relations is due to Kennard. He proved in 1927 the theorem that for all normalized state vectors $|\psi\rangle$ the following inequality holds:

$$\Delta_\psi \boldsymbol{p} \Delta_\psi \boldsymbol{q} \geq \frac{\hbar}{2} \tag{9}$$

Here, $\Delta_\psi \boldsymbol{p}$ and $\Delta_\psi \boldsymbol{q}$ are standard deviations of position and momentum in the state vector $|\psi\rangle$, i.e.,

$$(\Delta_\psi \boldsymbol{p})^2 = \langle \boldsymbol{p}^2 \rangle_\psi - \langle \boldsymbol{p} \rangle_\psi^2, \qquad (\Delta_\psi \boldsymbol{q})^2 = \langle \boldsymbol{q}^2 \rangle_\psi - \langle \boldsymbol{q} \rangle_\psi^2 \tag{10}$$

where $\langle \cdot \rangle_\psi = \langle \psi | \cdot | \psi \rangle$ denotes the expectation value in state $|\psi\rangle$. This inequality (10) was generalized in 1929 by Robertson who proved the result that for all observables (self-adjoint operators) $\boldsymbol{A}$ and $\boldsymbol{B}$

$$\Delta_\psi \boldsymbol{A} \Delta_\psi \boldsymbol{B} \geq \frac{1}{2} |\langle [\boldsymbol{A}, \boldsymbol{B}] \rangle_\psi| \tag{11}$$

where $[\boldsymbol{A}, \boldsymbol{B}] := \boldsymbol{AB} - \boldsymbol{BA}$ denotes the commutator. This relation was in turn strengthened by Schrödinger (1930), who obtained:

$$(\Delta_\psi \boldsymbol{A})^2 (\Delta_\psi \boldsymbol{B})^2 \geq \frac{1}{4} |\langle [\boldsymbol{A}, \boldsymbol{B}] \rangle_\psi|^2 + \frac{1}{4} |\langle \{ \boldsymbol{A} - \langle \boldsymbol{A} \rangle_\psi, \boldsymbol{B} - \langle \boldsymbol{B} \rangle_\psi \}] \rangle_\psi|^2 \tag{12}$$

where $\{A, B\} := (AB + BA)$ denotes the anti-commutator.

Since the above inequalities have the virtue of being exact and general, in contrast to Heisenberg's original semi-quantitative formulation, it is tempting to regard them as the exact counterpart of Heisenberg's relations (2)-(4). Indeed, such was Heisenberg's own view. In his Chicago Lectures (Heisenberg 1930, pp. 15-19), he presented Kennard's derivation of relation (9) and claimed that "this proof does not differ at all in mathematical content" from the semi-quantitative argument he had presented earlier, the only difference being that now "the proof is carried through exactly".

But it may be useful to point out that both in status and intended role there is a subtle difference between Kennard's inequality and Heisenberg's previous formulation (2). The inequalities discussed here are not statements of empirical fact, but theorems of the formalism. As such, they presuppose the validity of this formalism, and in particular the commutation relation (1), rather than elucidating its intuitive content or to create ‘room’ or ‘freedom’ for the validity of this relation. At best, one should see the above inequalities as showing that the formalism is consistent with Heisenberg's empirical principle.

This situation is similar to that arising in other theories of principle where, as noted in Section 2.4, one often finds that, next to an empirical principle, the formalism also provides a corresponding theorem. And similarly, this situation should not, by itself, cast doubt on the question whether Heisenberg's relation can be regarded as a principle of quantum mechanics.

There is a second notable difference between (2) and (9). Heisenberg did not give a general definition for the ‘uncertainties’ δp and δq. The most definite remark he made about them was that they could be taken as "something like the mean error". In the discussions of thought experiments, he and Bohr would always quantify uncertainties on a case-to-case basis by choosing some parameters which happened to be relevant to the experiment at hand. By contrast, the inequalities (9)-(12) employ a single specific expression as a measure for ‘uncertainty’: the standard deviation. This choice is not unnatural, given that this expression is well-known and widely used in error theory and the description of statistical fluctuations.

However, there was very little or no discussion of whether this choice was appropriate for the general formulation of the uncertainty relations. A standard deviation reflects the spread or expected fluctuations in a series of measurements of an observable on a given state. It is not at all easy to connect this idea with the concept of the ‘inaccuracy’ of a measurement, such as the resolving power of a microscope. In fact, even though Heisenberg had taken Kennard's inequality as the precise formulation of the uncertainty relation, he and Bohr never relied on standard deviations in their many discussions of thought experiments, and indeed, it has been shown (Uffink and Hilgevoord, 1985; Hilgevoord and Uffink, 1988) that these discussions cannot be framed in terms of standard deviation.

Another problem with the above elaboration is that it soon turned out that there are no analogous inequalities for time and energy, nor for action and angle. Jordan (1927) pointed out in 1927 that the ‘well-known’ relations (5) are actually false in the case of action and angle, and Pauli (1933) showed that there

is no operator canonically conjugate to the Hamiltonian, if the latter is bounded from below. This menas that for many systems a time operator does not exist. These observations have led to a quite extensive literature on time-energy and phase-action uncertainty relations, proposing many different attempts to overcome these obstacles.

3. Bohr

In spite of the fact that Heisenberg's and Bohr's views on quantum mechanics are often lumped together as (part of) ‘the Copenhagen interpretation’, there is considerable difference between their views on the uncertainty relations.

3.1 From wave-particle duality to complementarity

Long before the development of modern quantum mechanics, Bohr had been particularly concerned with the problem of particle-wave duality, i.e. the problem that experimental evidence on the behaviour of both light and matter seemed to demand a wave picture in some cases, and a particle picture in others. Yet these pictures are mutually exclusive. Whereas a particle is always localized, the very definition of the notions of wavelength and frequency requires an extension in space and in time. Moreover, the classical particle picture is incompatible with the characteristic phenomenon of interference.

His long struggle with wave-particle duality had prepared him for a radical step when the dispute between matrix and wave mechanics broke out in 1926-27. For the main contestants, Heisenberg and Schrödinger, the issue at stake was which view could claim to provide a single coherent and universal framework for the description of the observational data. The choice was, essentially between a description in terms of continuously evolving waves, or else one of particles undergoing discontinuous quantum jumps. By contrast, Bohr insisted that elements from both views were equally valid and equally needed for an exhaustive description of the data. His way out of the contradiction was to renounce the idea that the pictures refer, in a literal one-to-one correspondence, to physical reality. Instead, the applicability of these pictures was to become dependent on the experimental context. This is the gist of the viewpoint he called ‘complementarity’.

Bohr first conceived the general outline of his complementarity argument in early 1927, during a skiing holiday in Norway, at the same time when Heisenberg wrote his uncertainty paper. When he returned to Copenhagen and found Heisenberg's manuscript, they got into an intense discussion. On the one hand, Bohr was quite enthusiastic about Heisenberg's ideas which seemed to fit wonderfully with his own thinking. Indeed, in his subsequent work, Bohr always presented the uncertainty relations as the symbolic expression of his complementarity viewpoint. On the other hand, he criticized Heisenberg severely for his suggestion that these relations were due to discontinuous changes occurring during a measurement process. Rather, Bohr argued, their proper derivation should start from the indispensability of both particle and wave concepts. He pointed out that the uncertainties in the experiment did not exclusively arise from the discontinuities but also from the fact that in the experiment we need to take into account both the particle theory and the wave theory. It is not so much the unknown disturbance which renders

the momentum of the electron uncertain but rather the fact that the position and the momentum of the electron cannot be simultaneously defined in this experiment. (See the "Addition in Proof" to Heisenberg's paper.)

We shall not go too deeply into the matter of Bohr's interpretation of quantum mechanics since we are mostly interested in Bohr's view on the uncertainty principle. For a more detailed discussion of Bohr's philosophy of quantum physics we refer to Scheibe (1973), Folse (1985), Honner (1987) and Murdoch (1987). It may be useful, however, to sketch some of the main points. Central in Bohr's considerations is the *language* which we use in physics. No matter how abstract and subtle the concepts of modern physics may be, they are essentially an extension of our ordinary language and a means to communicate the results of our experiments. These results, obtained under well-defined experimental circumstances, are what Bohr calls the "phenomena". A phenomenon is "the comprehension of the effects observed under given experimental conditions" (Bohr 1939, p. 24), it is the resultant of a physical object, a measuring apparatus and the interaction between them in a concrete experimental situation. The essential difference between classical and quantum physics is that in quantum physics the interaction between the object and the apparatus cannot be made arbitrarily small; the interaction must at least comprise one quantum. This is expressed by Bohr's quantum postulate:

> [… the] essence [of the formulation of the quantum theory] may be expressed in the so-called quantum postulate, which attributes to any atomic process an essential discontinuity or rather individuality, completely foreign to classical theories and symbolized by Planck's quantum of action. (Bohr, 1928, p. 580)

A phenomenon, therefore, is an indivisible whole and the result of a measurement cannot be considered as an autonomous manifestation of the object itself independently of the measurement context. The quantum postulate forces upon us a new way of describing physical phenomena:

> In this situation, we are faced with the necessity of a radical revision of the foundation for the description and explanation of physical phenomena. Here, it must above all be recognized that, however far quantum effects transcend the scope of classical physical analysis, the account of the experimental arrangement and the record of the observations must always be expressed in common language supplemented with the terminology of classical physics. (Bohr, 1948, p. 313)

This is what Scheibe (1973) has called the "buffer postulate" because it prevents the quantum from penetrating into the classical description: A phenomenon must always be described in classical terms; Planck's constant does not occur in this description.

Together, the two postulates induce the following reasoning. In every phenomenon the interaction between the object and the apparatus comprises at least one quantum. But the description of the phenomenon must use classical notions in which the quantum of action does not occur. Hence, the interaction cannot be analysed in this description. On the other hand, the classical character of the

description allows to speak in terms of the object itself. Instead of saying: ‘the interaction between a particle and a photographic plate has resulted in a black spot in a certain place on the plate’, we are allowed to forgo mentioning the apparatus and say: ‘the particle has been found in this place’. The experimental context, rather than changing or disturbing pre-existing properties of the object, defines what can meaningfully be said about the object.

Because the interaction between object and apparatus is left out in our description of the phenomenon, we do not get the whole picture. Yet, any attempt to extend our description by performing the measurement of a different observable quantity of the object, or indeed, on the measurement apparatus, produces a new phenomenon and we are again confronted with the same situation. Because of the unanalyzable interaction in both measurements, the two descriptions cannot, generally, be united into a single picture. They are what Bohr calls complementary descriptions:

> [the quantum of action]...forces us to adopt a new mode of description designated as complementary in the sense that any given application of classical concepts precludes the simultaneous use of other classical concepts which in a different connection are equally necessary for the elucidation of the phenomena. (Bohr, 1929, p. 10)

The most important example of complementary descriptions is provided by the measurements of the position and momentum of an object. If one wants to measure the position of the object relative to a given spatial frame of reference, the measuring instrument must be rigidly fixed to the bodies which define the frame of reference. But this implies the impossibility of investigating the exchange of momentum between the object and the instrument and we are cut off from obtaining any information about the momentum of the object. If, on the other hand, one wants to measure the momentum of an object the measuring instrument must be able to move relative to the spatial reference frame. Bohr here assumes that a momentum measurement involves the registration of the recoil of some movable part of the instrument and the use of the law of momentum conservation. The looseness of the part of the instrument with which the object interacts entails that the instrument cannot serve to accurately determine the position of the object. Since a measuring instrument cannot be rigidly fixed to the spatial reference frame and, at the same time, be movable relative to it, the experiments which serve to precisely determine the position and the momentum of an object are mutually exclusive. Of course, in itself, this is not at all typical for quantum mechanics. But, because the interaction between object and instrument during the measurement can neither be neglected nor determined the two measurements cannot be combined. This means that in the description of the object one must choose between the assignment of a precise position or of a precise momentum.

Similar considerations hold with respect to the measurement of time and energy. Just as the spatial coordinate system must be fixed by means of solid bodies so must the time coordinate be fixed by means of unperturbable, synchronised clocks. But it is precisely this requirement which prevents one from taking into account of the exchange of energy with the instrument if this is to serve its purpose. Conversely, any conclusion about the object based on the conservation of energy prevents following its development in time.

The conclusion is that in quantum mechanics we are confronted with a complementarity between two descriptions which are united in the classical mode of description: the space-time description (or coordination) of a process and the description based on the applicability of the dynamical conservation laws. The quantum forces us to give up the classical mode of description (also called the ‘causal’ mode of description by Bohr[4]): it is impossible to form a classical picture of what is going on when radiation interacts with matter as, e.g., in the Compton effect.

> Any arrangement suited to study the exchange of energy and momentum between the electron and the photon must involve a latitude in the space-time description sufficient for the definition of wave-number and frequency which enter in the relation [$E = h\nu$ and $p = h\sigma$]. Conversely, any attempt of locating the collision between the photon and the electron more accurately would, on account of the unavoidable interaction with the fixed scales and clocks defining the space-time reference frame, exclude all closer account as regards the balance of momentum and energy. (Bohr, 1949, p. 210)

A causal description of the process cannot be attained; we have to content ourselves with complementary descriptions. "The viewpoint of complementarity may be regarded", according to Bohr, "as a rational generalization of the very ideal of causality".

In addition to complementary descriptions Bohr also talks about complementary phenomena and complementary quantities. Position and momentum, as well as time and energy, are complementary quantities.[5]

We have seen that Bohr's approach to quantum theory puts heavy emphasis on the language used to communicate experimental observations, which, in his opinion, must always remain classical. By comparison, he seemed to put little value on arguments starting from the mathematical formalism of quantum theory. This informal approach is typical of all of Bohr's discussions on the meaning of quantum mechanics. One might say that for Bohr the conceptual clarification of the situation has primary importance while the formalism is only a symbolic representation of this situation.

This is remarkable since, finally, it is the formalism which needs to be interpreted. This neglect of the formalism, certainly, is one of the reasons why it is so difficult to get a clear understanding of Bohr's interpretation of quantum mechanics and why it has aroused so much controversy. We close this section by citing from an article of 1948 to show how Bohr conceived the role of the formalism of quantum mechanics:

> The entire formalism is to be considered as a tool for deriving predictions, of definite or statistical character, as regards information obtainable under experimental conditions described in classical terms and specified by means of parameters entering into the algebraic or differential equations of which the matrices or the wave-functions, respectively, are solutions. These symbols themselves, as is indicated already by the use of imaginary numbers, are not susceptible to pictorial interpretation; and even derived real

> functions like densities and currents are only to be regarded as expressing the probabilities for the occurrence of individual events observable under well-defined experimental conditions. (Bohr, 1948, p. 314)

3.2 Bohr's view on the uncertainty relations

In his Como lecture, published in 1928, Bohr gave his own version of a derivation of the uncertainty relations between position and momentum and between time and energy. He started from the relations

$$E = h\nu \text{ and } p = h/\lambda \tag{13}$$

which connect the notions of energy E and momentum p from the particle picture with those of frequency ν and wavelength λ from the wave picture. He noticed that a wave packet of limited extension in space and time can only be built up by the superposition of a number of elementary waves with a large range of wave numbers and frequencies. Denoting the spatial and temporal extensions of the wave packet by Δx and Δt, and the extensions in the wave number $\sigma := 1/\lambda$ and frequency by $\Delta\sigma$ and $\Delta\nu$, it follows from Fourier analysis that in the most favorable case $\Delta x\Delta\sigma \approx \Delta t\Delta\nu \approx 1$, and, using (13), one obtains the relations

$$\Delta t\Delta E \approx \Delta x\Delta p \approx h \tag{14}$$

Note that Δx, $\Delta\sigma$, etc., are not standard deviations but unspecified measures of the size of a wave packet. (The original text has equality signs instead of approximate equality signs, but, since Bohr does not define the spreads exactly the use of approximate equality signs seems more in line with his intentions. Moreover, Bohr himself used approximate equality signs in later presentations.) These equations determine, according to Bohr: "the highest possible accuracy in the definition of the energy and momentum of the individuals associated with the wave field" (Bohr 1928, p. 571). He noted, "This circumstance may be regarded as a simple symbolic expression of the complementary nature of the space-time description and the claims of causality" (*ibid*).[6] We note a few points about Bohr's view on the uncertainty relations. First of all, Bohr does not refer to *discontinuous changes* in the relevant quantities during the measurement process. Rather, he emphasizes the possibility of *defining* these quantities. This view is markedly different from Heisenberg's. A draft version of the Como lecture is even more explicit on the difference between Bohr and Heisenberg:

> These reciprocal uncertainty relations were given in a recent paper of Heisenberg as the expression of the statistical element which, due to the feature of discontinuity implied in the quantum postulate, characterizes any interpretation of observations by means of classical concepts. It must be remembered, however, that the uncertainty in question is not simply a consequence of a discontinuous change of energy and momentum say during an interaction between radiation and material particles employed in measuring the space-time coordinates of the individuals. According to the above considerations the question is rather

> that of the impossibility of defining rigourously such a change when the space-time coordination of the individuals is also considered. (Bohr, 1985 p. 93)

Indeed, Bohr not only rejected Heisenberg's argument that these relations are due to discontinuous disturbances implied by the act of measuring, but also his view that the measurement process *creates* a definite result:

> The unaccustomed features of the situation with which we are confronted in quantum theory necessitate the greatest caution as regard all questions of terminology. Speaking, as it is often done of disturbing a phenomenon by observation, or even of creating physical attributes to objects by measuring processes is liable to be confusing, since all such sentences imply a departure from conventions of basic language which even though it can be practical for the sake of brevity, can never be unambiguous. (Bohr, 1939, p. 24)

Nor did he approve of an epistemological formulation or one in terms of experimental inaccuracies:

> […] a sentence like "we cannot know both the momentum and the position of an atomic object" raises at once questions as to the physical reality of two such attributes of the object, which can be answered only by referring to the mutual exclusive conditions for an unambiguous use of space-time concepts, on the one hand, and dynamical conservation laws on the other hand. (Bohr, 1948, p. 315; also Bohr 1949, p. 211)

> It would in particular not be out of place in this connection to warn against a misunderstanding likely to arise when one tries to express the content of Heisenberg's well-known indeterminacy relation by such a statement as 'the position and momentum of a particle cannot simultaneously be measured with arbitrary accuracy'. According to such a formulation it would appear as though we had to do with some arbitrary renunciation of the measurement of either the one or the other of two well-defined attributes of the object, which would not preclude the possibility of a future theory taking both attributes into account on the lines of the classical physics. (Bohr 1937, p. 292)

Instead, Bohr always stressed that in his point of view the uncertainty relations are foremost an expression of complementarity. At first sight, this might seem odd, since, after all, complementarity corresponds to a dichotomic relation between two types of description. The uncertainty relations "express" this dichotomy in the informal sense that if we take energy and momentum to be perfectly well-defined, i.e., symbolically $\Delta E = \Delta p = 0$, the position and time variables are completely undefined, $\Delta x = \Delta t = \infty$, and vice versa. However, by focussing on these extremes only, we leave out of consideration that the uncertainty relations also (and more properly) allow for an intermediate situation in which the mentioned uncertainties are all non-zero and finite. This more positive aspect of the uncertainty relation is mentioned in the Como lecture:

> At the same time, however, the general character of this relation makes it possible to a

> certain extent to reconcile the conservation laws with the space-time coordination of observations, the idea of a coincidence of well-defined events in space-time points being replaced by that of unsharply defined individuals within space-time regions. (Bohr 1928, p. 571)

However, Bohr never followed up on this suggestion that we might be able to strike a compromise between the two mutually exclusive modes of description in terms of unsharply defined quantities. Indeed, an attempt to do so, would take the formalism of quantum theory more seriously than the concepts of classical language, and this step Bohr refused to take. Instead, in his later writings he would be content with stating that the uncertainty relations simply defy an unambiguous interpretation in classical terms:

> These so-called indeterminacy relations explicitly bear out the limitation of causal analysis, but it is important to recognize that no unambiguous interpretation of such a relation can be given in words suited to describe a situation in which physical attributes are objectified in a classical way. (Bohr, 1948, p.315)

> It must here be remembered that even in the indeterminacy relation [$\Delta q \Delta p \approx h$] we are dealing with an implication of the formalism which defies unambiguous expression in words suited to describe classical pictures. Thus a sentence like "we cannot know both the momentum and the position of an atomic object" raises at once questions as to the physical reality of two such attributes of the object, which can be answered only by referring to the conditions for an unambiguous use of space-time concepts, on the one hand, and dynamical conservation laws on the other hand. (Bohr, 1949, p. 211)

Finally, on a more formal level, we note that Bohr's derivation does not rely on the commutation relations (1) and (5), but on Fourier analysis. To be sure, these two approaches are equivalent as far as the relationship between position and momentum is concerned. But this is not so for time and energy. This means that, for a derivation based on the commutation relations, the position-momentum and time-energy relations are not on an equal footing, which is contrary to Bohr's approach in terms of Fourier analysis (Hilgevoord, 1996 and 1998).

4. The Minimal Interpretation

In the previous two sections we have seen how both Heisenberg and Bohr attributed a far-reaching status to the uncertainty relations. They both argued that these relations place fundamental limits on the applicability of the usual classical concepts. Moreover, they both believed that these limitations were inevitable and forced upon us. However, we have also seen that they reached such conclusions by starting from radical and controversial assumptions. This entails, of course, that their radical conclusions remain unconvincing for those who reject these, or other assumptions. Indeed, the operationalist-positivist viewpoint adopted by these authors has long since lost its appeal among philosophers of physics.

So the question may be asked what alternative views of the uncertainty relations are still viable. Of course, this problem is intimately connected with that of the interpretation of the wave function, and hence of quantum mechanics as a whole. Since there is no consensus about the latter, one cannot expect consensus about the interpretation of the uncertainty relations either. Here we only describe a point of view, which we call the 'minimal interpretation', which seems to be shared by both the adherents of the Copenhagen interpretation and of other views.

In quantum mechanics a system is supposed to be described by its quantum state, also called its state vector. Given the state vector, one can derive probability distributions for all the physical quantities pertaining to the system such as its position, momentum, angular momentum, energy, etc. The operational meaning of these probability distributions is that they correspond to the distribution of the values obtained for these quantities in a long series of repetitions of the measurement. More precisely, one imagines a great number of copies of the system under consideration, all prepared in the same way. On each copy the momentum, say, is measured. Generally, the outcomes of these measurements differ and a distribution of outcomes is obtained. The theoretical momentum distribution derived from the quantum state is supposed to coincide with the hypothetical distribution of outcomes obtained in an infinite series of repetitions of the momentum measurement. The same holds, *mutatis mutandis*, for all the other physical quantities pertaining to the system. Note that no simultaneous measurements of two or more quantities are required in defining the operational meaning of the probability distributions.

Uncertainty relations can be considered as statements about the spreads of the probability distributions of the several physical quantities arising from the same state. For example, the uncertainty relation between the position and momentum of a system may be understood as the statement that the position and momentum distributions cannot both be arbitrarily narrow -- in some sense of the word "narrow" -- in any quantum state. Inequality (9) is an example of such a relation in which the standard deviation is employed as a measure of spread. From this characterization of uncertainty relations follows that a more detailed interpretation of the quantum state than the one given in the previous paragraph is not required to study uncertainty relations as such. In particular, a further ontological or linguistic interpretation of the notion of uncertainty, as limits on the applicability of our concepts given by Heisenberg or Bohr, need not be supposed.

Indeed, this minimal interpretation leaves open whether it makes sense to attribute precise values of position and momentum to an individual system. Some interpretations of quantum mechanics, e.g. Heisenberg and Bohr, deny this; while others, e.g. the interpretation of de Broglie and Bohm insist that each individual system has a definite position and momentum. The only requirement is that, as an empirical fact, it is not possible to prepare pure ensembles in which all systems have the same values for these quantities, or ensembles in which the spreads are smaller than allowed by quantum theory. Although interpretations of quantum mechanics, in which each system has a definite value for its position and momentum are still viable, this is not to say that they are without problems or, at least strange features, of their own. They do not imply a return to classical physics.

We end with a few remarks on this minimal interpretation. First, it may be noted that the minimal interpretation of the uncertainty relations is little more than filling in the empirical meaning of inequality

(9), or an inequality in terms of other measures of width, as obtained from the standard formalism of quantum mechanics. As such, this view shares many of the limitations we have noted above about this inequality. Indeed, it is not straightforward to relate the spread in a statistical distribution of measurement results with the *inaccuracy* of this measurement, such as, e.g. the resolving power of a microscope. Moreover, the minimal interpretation does not address the question whether one can make *simultaneous* accurate measurements of position and momentum. As a matter of fact, one can show that the standard formalism of quantum mechanics does not allow such simultaneous measurements. But this is not a consequence of relation (9).

If one feels that statements about inaccuracy of measurement, or the possibility of simultaneous measurements, belong to any satisfactory formulation of the uncertainty principle, the minimal interpretation may thus be too minimal.

Notes to Uncertainty Relations in Quantum Theory

Notes

1. The translation of *anschaulich* as ‘intuitive’ is obviously the best candidate, since it has a corresponding etymological root. Unfortunately, this term is often used to refer to a kind of understanding which bypasses reasoning. This is not intended here.

2. Although this claim by Schrödinger seems to have been accepted by his contemporaries, his argument was incomplete. A satisfactory proof of the equivalence of wave mechanics and matrix mechanics was only provided later, when von Neumann (1932) showed that both approaches could be seen as different realisations of an abstract Hilbert space formalism. (See Muller, 1997, for historical details.)

3. However, the first draft of his paper, which he sent as a letter to Pauli (Pauli, 1979 pp. 376-382) shows that Heisenberg did have the outlines of a general, albeit qualitative, mathematical argument.

4. Note that this usage of the term ‘causal’ by Bohr differs from his usage of that term in earlier texts, where it refers only to the applicability of dynamical conservation laws, and not to the union of a space-time description with these conservation laws. Thus, in (Bohr, 1928), he characterized complementarity as a relation between space-time description and causality.

5. Note, that while Bohr started from the duality between the particle and wave pictures, which are mutually exclusive also in classical physics, he later considered as complementary two descriptions which in the classical theory are united.

6. See footnote 4 for Bohr's usage of the term ‘causality’.

The Many-Worlds Interpretation of Quantum Mechanics

The Many-Worlds Interpretation (MWI) is an approach to quantum mechanics according to which, in addition to the world we are aware of directly, there are many other similar worlds which exist in parallel at the same space and time. The existence of the other worlds makes it possible to remove randomness and action at a distance from quantum theory and thus from all physics.

1. Introduction

The fundamental idea of the MWI, going back to Everett 1957, is that there are myriads of worlds in the Universe in addition to the world we are aware of. In particular, every time a quantum experiment with different outcomes with non-zero probability is performed, all outcomes are obtained, each in a different world, even if we are aware only of the world with the outcome we have seen. In fact, quantum experiments take place everywhere and very often, not just in physics laboratories: even the irregular blinking of an old fluorescent bulb is a quantum experiment.

There are numerous variations and reinterpretations of the original Everett proposal, most of which are briefly discussed in the entry on Everett's relative state formulation of quantum mechanics. Here, a particular approach to the MWI (which differs from the popular "actual splitting worlds" approach in De Witt 1970) will be presented in detail, followed by a discussion relevant for many variants of the MWI.

The MWI consists of two parts:

i. A mathematical theory which yields evolution in time of the quantum state of the (single) Universe.
ii. A prescription which sets up a correspondence between the quantum state of the Universe and our experiences.

Part (i) is essentially summarized by the Schrödinger equation or its relativistic generalization. It is a rigorous mathematical theory and is not problematic philosophically. Part (ii) involves "our experiences" which do not have a rigorous definition. An additional difficulty in setting up (ii) follows from the fact that human languages were developed at a time when people did not suspect the existence of parallel worlds. This, however, is only a semantic problem.[1]

2. Definitions

2.1 What is "A World"?

> *A world is the totality of (macroscopic) objects: stars, cities, people, grains of sand, etc. in a definite classically described state.*

This definition is based on the common attitude to the concept of world shared by human beings.

Another concept (considered in some approaches as the basic one, e.g., in Saunders 1995) is a relative, or perspectival, world defined for every physical system and every one of its states (provided it is a state of non-zero probability): I will call it a *centered world*. This concept is useful when a world is centered on a

perceptual state of a sentient being. In this world, all objects which the sentient being perceives have definite states, but objects that are not under her observation might be in a superposition of different (classical) states. The advantage of a centered world is that it does not split due to a quantum phenomenon in a distant galaxy, while the advantage of our definition is that we can consider a world without specifying a center, and in particular our usual language is just as useful for describing worlds at times when there were no sentient beings.

The concept of "world" in the MWI belongs to part (ii) of the theory, i.e., it is not a rigorously defined mathematical entity, but a term defined by us (sentient beings) in describing our experience. When we refer to the "definite classically described state" of, say, a cat, it means that the position and the state (alive, dead, smiling, etc.) of the cat is maximally specified according to our ability to distinguish between the alternatives and that this specification corresponds to a classical picture, e.g., no superpositions of dead and alive cats are allowed in a single world.[2]

The concept of a world in the MWI is based on the layman's conception of a world; however, several features are different:

Obviously, the definition of the world as *everything that exists* does not hold in the MWI. "Everything that exists" is the Universe, and there is only one Universe. The Universe incorporates many worlds similar to the one the layman is familiar with.

Nowadays, the layman knows that objects are made of elementary microscopic particles, and he believes that, consequently, a more precise definition of the world is the totality of all these particles. In the MWI this naive step is incorrect. Microscopic particles might be in a superposition, while objects within a world (as defined in the MWI) cannot be in a superposition. The connection between macroscopic objects defined according to our experience, and microscopic objects defined in a physical theory that aims to explain our experience, is more subtle, and will be discussed further below. The definition of a world in the MWI involves only concepts related to our experience.

A layman believes that our present world has a unique past and future. According to the MWI, a world defined at some moment of time corresponds to a unique world at a time in the past, but to a multitude of worlds at a time in the future.

2.2 Who am "I"?

"I" am an object, such as Earth, cat, etc. "I" is defined at a particular time by a complete (classical) description of the state of my body and of my brain. "I" and "Lev" do not name the same things (even though my name is Lev). At the present moment there are many different "Lev"s in different worlds (not more than one in each world), but it is meaningless to say that now there is another "I". I have a particular, well defined past: I correspond to a particular "Lev" in 2002, but I do not have a well defined future: I correspond to a multitude of "Lev"s in 2010. In the framework of the MWI it is meaningless to ask: Which Lev in 2010 will I be? I will correspond to them all. Every time I perform a quantum

experiment (with several possible results) it only seems to me that I obtain a single definite result. Indeed, Lev who obtains this particular result thinks this way. However, this Lev cannot be identified as the only Lev after the experiment. Lev before the experiment corresponds to all "Lev"s obtaining all possible results. Although this approach to the concept of personal identity seems somewhat unusual, it is plausible in the light of the critique of personal identity by Parfit 1986. Parfit considers some artificial situations in which a person splits into several copies, and argues that there is no good answer to the question: Which copy is me? He concludes that personal identity is not what matters when I divide.

3. Correspondence Between the Formalism and Our Experience

3.1 The Quantum State of an Object

The basis for the correspondence between the quantum state (the wave function) of the Universe and our experience is the description that physicists give in the framework of standard quantum theory for objects composed of elementary particles. Elementary particles of the same kind are identical. Therefore, the essence of an object is the quantum state of its particles and not the particles themselves (see the elaborate discussion in the entry on identity and individuality in quantum theory): one quantum state of a set of elementary particles might be a cat and another state of the same particles might be a small table. Clearly, we cannot now write down an exact wave function of a cat. We know with a reasonable approximation the wave function of some elementary particles that constitute a nucleon. The wave function of the electrons and the nucleons that together make up an atom is known with even better precision. The wave functions of molecules (i.e. the wave functions of the ions and electrons out of which molecules are built) are well studied. A lot is known about biological cells, so physicists can write down a rough form of the quantum state of a cell. This is difficult because there are many molecules in a cell. Out of cells we construct various tissues and then the whole body of a cat or of a table. So, let us denote the quantum state constructed in this way $|\Psi\rangle_{OBJECT}$.

In our construction $|\Psi\rangle_{OBJECT}$ is the quantum state of an object in a definite state and position.[3] According to the definition of a world we have adopted, in each world the cat is in a definite state: either alive or dead. Schrödinger's experiment with the cat leads to a splitting of worlds even before opening the box. Only in the alternative approach is Schrödinger's cat, which is in a superposition of being alive and dead, a member of the (single) centered world of the observer before she opened the sealed box with the cat (the observer perceives directly the facts related to the preparation of the experiment and she deduces that the cat is in a superposition).

3.2 The Quantum State that corresponds to a World

The wave function of all particles in the Universe corresponding to any particular world will be a product

of states of sets of particles corresponding to all objects in the world multiplied by the quantum state $|\Phi\rangle$ of all the particles that do not constitute "objects". Within a world, "objects" have definite macroscopic states by fiat:[4]

$$|\Psi_{\text{WORLD}}\rangle = |\Psi\rangle_{\text{OBJECT 1}} |\Psi\rangle_{\text{OBJECT 2}} \ldots |\Psi\rangle_{\text{OBJECT } N} \quad |\Phi\rangle \qquad (1)$$

The quantum states corresponding to centered worlds of sentient beings have exactly the same form. The only difference is that in the product there are only states of the objects perceived directly, while most of the universe is, in general, entangled; it is described by $|\Phi\rangle$.

3.3 The Quantum State of the Universe

The quantum state of the Universe can be decomposed into a superposition of terms corresponding to different worlds:

$$|\Psi_{\text{UNIVERSE}}\rangle = \sum \alpha_i |\Psi_{\text{WORLD } i}\rangle \qquad (2)$$

Different worlds correspond to different classically described states of at least one object. Different classically described states correspond to orthogonal quantum states. Therefore, different worlds correspond to orthogonal states: all states $|\Psi_{\text{WORLD } i}\rangle$ are mutually orthogonal and consequently, $\sum|\alpha_i|^2 = 1$.

3.4 FAPP

The construction of the quantum state of the Universe in terms of the quantum states of objects presented above is only approximate, it is good only *for all practical purposes* (FAPP). Indeed, the concept of an object itself has no rigorous definition: should a mouse that a cat just swallowed be considered as a part of the cat? The concept of a "definite position" is also only approximately defined: how far should a cat be displaced in order for it to be considered to be in a different position? If the displacement is much smaller than the quantum uncertainty, it must be considered to be at the same place, because in this case the quantum state of the cat is almost the same and the displacement is undetectable in principle. But this is only an absolute bound, because our ability to distinguish various locations of the cat is far from this quantum limit. Further, the state of an object (e.g. alive or dead) is meaningful only if the object is considered for a period of time. In our construction, however, the quantum state of an object is defined at a particular time. In fact, we have to ensure that the quantum state will have the shape of the object not only at that time, but for some period of time. Splitting of the world during this period of time is another source of ambiguity, in particular, due to the fact that there is no precise definition of when the splitting occurs.

The reason that I am only able to propose an approximate prescription for correspondence between the quantum state of the Universe and our experience, is essentially the same that led Bell 1990 to claim that "ordinary quantum mechanics is just fine FAPP". The concepts we use: "object", "measurement", etc. are not rigorously defined. Bell was, and many others are looking (until now in vain) for a "precise quantum mechanics". Since it is not enough for a physical theory to be just fine FAPP, a quantum mechanics needs rigorous foundations. However, in the MWI just fine FAPP is enough. Indeed, the MWI has rigorous foundations for (i), the "physics part" of the theory; only part (ii), the correspondence with our experience, is approximate (just fine FAPP). But "just fine FAPP" means that the theory explains our experience for any possible experiment, and this is the goal of (ii). See Butterfield 2001 and Wallace 2001b for more arguments why a FAPP definition of a world ("branch" in their language) is enough.

3.5 The Measure of Existence

There are many worlds existing in parallel in the Universe. Although all worlds are of the same physical size (this might not be true if we take quantum gravity into account), and in every world sentient beings feel as "real" as in any other world, in some sense some worlds are larger than others. I describe this property as the *measure of existence* of a world.[5] The measure of existence of a world quantifies its ability to interfere with other worlds in a gedanken experiment, see Vaidman 1998 (p. 256), and is the basis for introducing *probability* in the MWI. The measure of existence makes precise what is meant by the probability measure discussed in Everett 1957 and pictorially described in Lockwood 1989 (p. 230).

Given the decomposition (2), the measure of existence of the world i is $\mu_i = |\alpha_i|^2$. It also can be expressed as the expectation value of $\mathbf{P}_i$, the projection operator on the space of quantum states corresponding to the actual values of all physical variables describing the world i:

$$\mu_i \equiv \langle \Psi_{\mathrm{UNIVERSE}} | \mathbf{P}_i | \Psi_{\mathrm{UNIVERSE}} \rangle \qquad (3)$$

"I" also have a measure of existence. It is the sum of measures of existence of all different worlds in which I exist; equally, it can be defined as the measure of existence of my perception world. Note that I do not experience directly the measure of my existence. I feel the same weight, see the same brightness, etc. irrespectively of how tiny my measure of existence might be.

4. Probability in the MWI

There is a serious difficulty with the concept of probability in the context of the MWI. In a deterministic theory, such as the MWI, the only possible meaning for probability is an *ignorance* probability, but there is no relevant information that an observer who is going to perform a quantum experiment is ignorant about. The quantum state of the Universe at one time specifies the quantum state at all times. If I am going to perform a quantum experiment with two possible outcomes such that standard quantum

mechanics predicts probability 1/3 for outcome A and 2/3 for outcome B, then, according to the MWI, both the world with outcome A and the world with outcome B will exist. It is senseless to ask: "What is the probability that I will get A instead of B?" because I will correspond to both "Lev"s: the one who observes A and the other one who observes B.[6]

To solve this difficulty, Albert and Loewer 1988 proposed the Many Minds interpretation (in which the different worlds are only in the minds of sentient beings). In addition to the quantum wave of the Universe, Albert and Loewer postulate that every sentient being has a continuum of minds. Whenever the quantum wave of the Universe develops into a superposition containing states of a sentient being corresponding to different perceptions, the minds of this sentient being evolve randomly and independently to mental states corresponding to these different states of perception (with probabilities equal to the quantum probabilities for these states). In particular, whenever a measurement is performed by an observer, the observer’s minds develop mental states that correspond to perceptions of the different outcomes, i.e. corresponding to the worlds A or B in our example. Since there is a continuum of minds, there will always be an infinity of minds in any sentient being and the procedure can continue indefinitely. This resolves the difficulty: each "I" corresponds to one mind and it ends up in a state corresponding to a world with a particular outcome. However, this solution comes at the price of introducing additional structure into the theory, including a genuinely random process.

Vaidman1998 (p. 254) resolves the problem by constructing an *ignorance probability* in the framework of the MWI. It seems senseless to ask: "What is the probability that Lev in the world A will observe A?" This probability is trivially equal to 1. The task is to define the probability in such a way that we could reconstruct the prediction of the standard approach: probability 1/3 for A. It is indeed senseless *for you* to ask what is the probability that Lev in the world A will observe A, but this might be a meaningful question for Lev in the world of the outcome A. Under normal circumstances, the world A is created (i.e. measuring devices and objects which interact with measuring devices will become localized according to the outcome A) before Lev will be aware of the result A. Then, it is sensible to ask this Lev about his probability to be in world A. There is a matter of fact about which outcome this Lev will see, but he is ignorant about this fact at the time of the question. In order to make this point vivid, Vaidman proposed an experiment in which the experimenter is given a sleeping pill before the experiment. Then, while asleep, he is moved to room A or to room B depending on the results of the experiment. When the experimenter has woken up (in one of the rooms), but before he has opened his eyes, he is asked "In which room are you?" Certainly, there is a matter of fact about which room he is in (he can learn about it by opening his eyes), but he is ignorant about this fact at the time of the question. This construction provides the ignorance interpretation of probability, but the value of the probability has to be postulated (see Section 6.3 below for attempts to derive it):

> **Probability Postulate**
> The probability of an outcome of a quantum experiment is proportional to the total measure of existence of all worlds with that outcome.[7]

The question of the probability of obtaining A also makes sense for the Lev in world B before he

becomes aware of the outcome. Both "Lev"s have the same information on the basis of which they should give their answer. According to the probability postulate they will give the *same* answer: 1/3 (the relative measure of existence of the world A). Since Lev before the measurement is associated with two "Lev"s after the measurement who have identical ignorance probability concepts for the outcome of the experiment, I can define the probability of the outcome of the experiment to be performed as the ignorance probability of the successors of Lev for being in a world with a particular outcome.

The "sleeping pill" argument does not reduce the probability of an outcome of a quantum experiment to a familiar concept of probability in the classical context. The quantum situation is genuinely different. Since all outcomes of a quantum experiment are actualized, there is no probability in the usual sense. The argument explains the Behavior Principle (see below) for an experimenter according to which he should behave as if there were certain probabilities for different outcomes. The justification is particularly clear in the approach to probability as the value of a rational bet on a particular result. The results of the betting of the experimenter are relevant for his successors emerging after performing the experiment in different worlds. Since the experimenter is related to all of his successors and they all have identical rational strategies for betting, then, this should also be the strategy of the experimenter before the experiment.

Several authors justify the probability postulate without relying on the sleeping pill argument. Tappenden 2000 (p. 111) adopts a different semantics according to which "I" live in all branches and have "distinct experiences" in different "superslices", and uses "weight of a superslice" instead of measure of existence. He argues that it is intelligible to associate probabilities according to the probability postulate: "Faced with an array of weighted superslices as part of myself ... what choice do I have but to assign an array of attitudes, degrees of belief, towards the experiences associated with those superslices?". Saunders 1998, exploiting a variety of ideas in decoherence theory, the relational theory of tense and theories of identity over time, also argues for "identification of probability with the Hilbert Space norm" (which equals the measure of existence). Page 2002 promotes an approach which he has recently named *Mindless Sensationalism*. The basic concept in this approach is a conscious experience. He assigns *weights* to different experiences depending on the quantum state of the universe, as the expectation values of presently-unknown positive operators corresponding to the experiences (similar to the measures of existence of the corresponding worlds (3)). Page writes "... experiences with greater weights exist in some sense more ..." In all of these approaches, the postulate is justified by appeal to an analogy with treatments of time, e.g., the measure of existence of a world is analogous to the duration of a time interval. In a more ambitious work, Deutsch 1999 has claimed to derive the probability postulate from the quantum formalism and the classical decision theory, but it is far from clear that he achieves this (see Barnum *et al.*).

5. Tests of the MWI

Despite the name "interpretation", the MWI is a variant of quantum theory that is different from others. Experimentally, the difference is relative to collapse theories. It seems that there is no experiment

distinguishing the MWI from other no-collapse theories such as Bohmian mechanics or other variants of MWI.

The collapse leads to effects that are, in principle, observable; these effects do not exist if the MWI is the correct theory. To observe the collapse we would need a super technology, which allows "undoing" a quantum experiment, including a reversal of the detection process by macroscopic devices. See Lockwood 1989 (p. 223), Vaidman 1998 (p. 257), and other proposals in Deutsch 1986. These proposals are all for gedanken experiments that cannot be performed with current or any foreseen future technology. Indeed, in these experiments an interference of different worlds has to be observed. Worlds are different when at least one macroscopic object is in macroscopically distinguishable states. Thus, what is needed is an interference experiment with a macroscopic body. Today there are interference experiments with larger and larger objects (e.g., fullerene molecules C_{60}), but these objects are still not large enough to be considered "macroscopic". Such experiments can only refine the constraints on the boundary where the collapse might take place. A decisive experiment should involve the interference of states which differ in a macroscopic number of degrees of freedom: an impossible task for today's technology.[8]

The collapse mechanism seems to be in contradiction with basic physical principles such as relativistic covariance, but nevertheless, some ingenious concrete proposals have been made (see Pearle 1986 and the entry on collapse theories). These proposals (and Weissman's 1999 non-linear MW idea) have additional observable effects, such as a tiny energy non-conservation, that were tested in several experiments. The effects were not found and some (but not all!) of these models have been ruled out.

In most no-collapse interpretations, the evolution of the quantum state of the Universe is the same. Still, one might imagine that there is an experiment distinguishing the MWI from another no-collapse interepretation based on the difference in the correspondence between the formalism and the experience (the results of experiments).

An apparent candidate for such an experiment is a setup proposed in Englert *et al*. 1992 in which a Bohmian world is different from the worlds of the MWI (see also Aharonov and Vaidman 1996). In this example, the Bohmian trajectory of a particle in the past is contrary to the records of seemingly good measuring devices (such trajectories were named *surrealistic*). However, at present, there are no memory records that can determine unambiguously (without deduction from a particular theory) the particle trajectory in the past. Thus, this difference does not lead to an experimental way of distinguishing between the MWI and Bohmian mechanics. I believe that no other experiment can distinguish between the MWI and other no-collapse theories either, except for some perhaps exotic modifications, e.g., Bohmian mechanics with initial particle position distribution deviating from the quantum distribution.

There are other opinions about the possibility of testing the MWI. It has frequently been claimed, e.g. by De Witt 1970, that the MWI is in principle indistinguishable from the ideal collapse theory. On the other hand, Plaga 1997 claims to have a realistic proposal for testing the MWI, and Page 2000 argues that

certain cosmological observations might support the MWI.

6. Objections to the MWI

Some of the objections to the MWI follow from misinterpretations due to the multitude of various MWIs. The terminology of the MWI can be confusing: "world" is "universe" in Deutsch 1996, while "universe" is "multiverse", etc. There are two very different approaches with the same name "The Many-Minds Interpretation (MMI)". The Albert and Loewer 1988 MMI mentioned above should not be confused with Lockwood' 1996 MMI (which resembles the approach of Zeh 1981). The latter is much closer to the MWI as it is presented here, see Sec. 17 of Vaidman 1998. Further, the MWI in the Heisenberg representation (Deutsch 2001) differs significantly from the MWI presented in the Schrödinger representation (used here). The MWI presented here is very close to Everett's original proposal, but in the entry on Everett's relative state formulation of quantum mechanics, as well as in his book Barrett 1999, Barrett uses the name "MWI" for the splitting worlds view publicized by De Witt 1970. This approach has been justly criticized: it has both some kind of collapse (an irreversible splitting of worlds in a preferred basis) and the multitude of worlds. Now I consider the main objections in detail.

6.1 Ockham's Razor

It seems that the majority of the opponents of the MWI reject it because, for them, introducing a very large number of worlds that we do not see is an extreme violation of Ockham's principle: "Entities are not to be multiplied beyond necessity". However, in judging physical theories one could reasonably argue that one should not multiply physical laws beyond necessity either (such a verion of Ockham's Razor has been applied in the past), and in this respect the MWI is the most economical theory. Indeed, it has all the laws of the standard quantum theory, but without the collapse postulate, the most problematic of physical laws. The MWI is also more economic than Bohmian mechanics which has in addition the ontology of the particle trajectories and the laws which give their evolution. Tipler 1986 (p. 208) has presented an effective analogy with the criticism of Copernican theory on the grounds of Ockham's razor.

One might consider also a possible philosophical advantage of the plurality of worlds in the MWI, similar to that claimed by realists about possible worlds, such as Lewis 1986 (see the discussion of the analogy between the MWI and Lewis's theory by Skyrms 1976). However, the analogy is not complete: Lewis' theory considers all logically possible worlds, many more than all worlds incorporated in the quantum state of the Universe.

6.2 The Problem of the Preferred Basis

A common criticism of the MWI stems from the fact that the formalism of quantum theory allows infinitely many ways to decompose the quantum state of the Universe into a superposition of orthogonal

states. The question arises: "Why choose the particular decomposition (2) and not any other?" Since other decompositions might lead to a very different picture, the whole construction seems to lack predictive power.

Indeed, the mathematical structure of the theory (i) does not yield a particular basis. The basis for decomposition into worlds follows from the common concept of a world according to which it consists of objects in definite positions and states ("definite" on the scale of our ability to distinguish them). In the alternative approach, the basis of a centered world is defined directly by an observer. Therefore, given the nature of the observer and given her concepts for describing the world, the particular choice of the decomposition (2) follows (up to a precision which is good FAPP, as required). If we do not ask why we are what we are, and why the world we perceive is what it is, but only how to explain relations between the events we observe in our world, then the problem of the preferred basis does not arise: we and the concepts of our world define the preferred basis.

But a stronger response can be made to this criticism. Looking at the details of the physical world, the structure of the Hamiltonian, the value of the Planck constant, etc., one can argue why the sentient beings we know are of a particular type and why they have the particular concepts they do for describing their worlds. The main argument is that the locality of interactions yields *stability* of worlds in which objects are well localized. The small value of the Planck constant allows macroscopic objects to be well localized for a considerable period of time. Thus, such worlds (corresponding to quantum states $|\Psi_i\rangle$) can maintain their macroscopic description long enough to be perceived by sentient beings. By constrast, a "world" with macroscopic objects being in a superposition of macroscopically distinguishable states (corresponding to a quantum state $1/\sqrt{2}(|\Psi_1\rangle+|\Psi_2\rangle)$ evolves during an extremely small time, much smaller than the perception time of any feasible sentient being, into a mixture with the other "world" $1/\sqrt{2}(|\Psi_1\rangle-|\Psi_2\rangle)$ (see Zurek 1998).

This is a good argument why sentient beings perceive localized objects and not superpositions, but one cannot rely on the decoherence argument alone in order to single out the proper basis. (See some technical difficulties in Barvinsky and Kamenshchik 1995.) The fact that we can perceive only well localized objects in definite macroscopic states might not be just a physics issue: chemistry, biology, and even psychology might be needed to account for our evolution. See various attempts to construct a theory of evolution of sentient beings based on the MWI or its variants in Albert 1992, Chalmers 1996, Deutsch 1996, Donald 1990, Gell-Mann and Hartle 1990, Lehner 1997, Lockwood 1989, Page 2002, Penrose 1994, Saunders 1994, and Zeh 1981.

6.3 Derivation of the Probability Postulate from the Formalism of the MWI

Besides the question of the interpretation of the probability measure, which we have treated above, there is a separate issue about probabilities in the MWI, namely the claim that was sometimes made, e.g. by De

Witt 1970, that the probability postulate, i.e. the postulate that the probability measure is proportional to the measure of existence, can be derived from the formalism of the MWI. Several authors, e.g., Kent 1990, criticize the MWI on the grounds that this claim fails. As a matter of fact, the MWI has no advantage over other interpretations with regard to this issue. What is true instead is that one *can* derive the Probability Postulate from a weaker postulate according to which the probability is a function of the measure of existence. The derivation can be based on Gleason's 1957 theorem about the uniqueness of the probability measure. Similar results can be achieved by the analysis of the frequency operator originated by Hartle 1968 and from more general arguments by Deutsch 1999. All these results can be derived in the framework of various interpretations and thus the success or failure of these proofs cannot be an argument in favor or against the MWI. The MWI, like all other interpretations, requires a probability postulate.

Another idea for obtaining a probability law out of the formalism is to state, by analogy to the frequency interpretation of classical probability, that the probability of an outcome is proportional to the number of worlds with this outcome. This proposal immediately yields predictions that are different from what we observe in experiments. Some authors, arguing that counting is the only sensible way to introduce probability, consider this to be a fatal difficulty for the MWI, e.g., Ballentine 1975. Graham 1973 suggested that the counting of worlds *does* yield correct probabilities if one takes into account detailed splitting of the worlds in realistic experiments, but other authors have criticized the MWI because of the failure of Graham's claim. Weissman 1999 has proposed a modification of quantum theory with additional non-linear decoherence (and hence even more worlds than standard MWI), which can lead asymptotically to worlds of equal mean measure for different outcomes. Although this avoids random processes, like other MWI's, the price in the complication of the mathematical theory seems to be too high for the simplification in explaining probability. I believe that assigning equal probability to every world is unjustified. The formalism of quantum theory includes different amplitudes for quantum states corresponding to different worlds. It is a positive feature of the theory that the differences in the mathematical descriptions of worlds (different absolute values of amplitudes) are manifest in our experience. See Saunders 1998 for a detailed analysis of this issue.

From the weak probability postulate (the probability is a function of the measure of existence) follows that in case all the worlds in which a particular experiment took place have equal measures of existence, the probability of an outcome *is* proportional to the number of worlds with this outcome. If the measures of existence of these worlds are not equal, the experimenters in all the worlds can perform additional auxiliary measurements of some variables such that all the new worlds will have equal measures of existence. The experimenters should be completely indifferent to the results of these auxiliary measurements: their only purpose is to split the worlds into "equal-weight" worlds. This procedure reconstructs the standard quantum probability rule from the counting worlds approach; see Deutsch 1999 for details.

6.4 Social Behavior of a Believer in the MWI

There are claims that a believer in the MWI will behave in an irrational way. One claim is based on the naive argument described in the previous section: a believer who assigns equal probabilities to all different worlds will bet equal bets for the outcomes of quantum experiments that have unequal probabilities.

Another claim, recently discussed by Lewis 2000, is related to the strategy of a believer in the MWI who is offered to play a *quantum Russian roulette* game. The argument is that I, who would not accept an offer to play a classical Russian roulette, should agree to play the roulette any number of times if the triggering occurs according to the outcome of a quantum experiment. Indeed, at the end, there will be one world in which Lev is a multi-millionaire and all other worlds in which there will be no Lev Vaidman alive. Thus, in the future, Lev will be rich and presumably a happy man.

However, adopting the Probability Postulate leads all believers in the MWI to behave according to the following principle:

> **Behavior Principle**
> We care about all our successive worlds in proportion to their measures of existence.

With this principle our behavior will be similar to the behavior of a believer in the collapse theory who cares about possible future worlds according to the probability of their occurrence. I should not agree to play quantum Russian roulette because the measure of existence of worlds with Lev dead will be much larger than the measure of existence of the worlds with rich Lev alive.

7. Why the MWI?

The reason for adopting the MWI is that it avoids the collapse of the quantum wave. (Other non-collapse theories are not better than MWI for various reasons, e.g., nonlocality of Bohmian mechanics; and the disadvantage of all of them is that they have some additional structure.) The collapse postulate is a physical law that differs from all known physics in two aspects: it is genuinely random and it involves some kind of action at a distance. According to the collapse postulate the outcome of a quantum experiment is not determined by the initial conditions of the Universe prior to the experiment: only the probabilities are governed by the initial state. Moreover, Bell 1964 has shown that there cannot be a compatible local-variables theory that will make deterministic predictions. There is no experimental evidence in favor of collapse and against the MWI. We need not assume that Nature plays dice. The MWI is a deterministic theory for a physical Universe and it explains why a world appears to be indeterministic for human observers.

The MWI exhibits some kind of nonlocality: "world" is a nonlocal concept, but it avoids action at a distance and, therefore, it is not in conflict with the relativistic quantum mechanics; see discussions of nonlocality in Vaidman 1994, Tipler 2000, Bacciagaluppi 2002, and Hemmo and Pitowsky 2001. Although the issues of (non)locality are most transparent in the Schrödinger representation, an additional

insight can be gained through recent analysis in the framework of the Heisenberg representation, see Deutsch and Hayden 2000, Rubin 2001, and Deutsch 2001. The most celebrated example of nonlocality was given by Bell 1964 in the context of the Einstein-Podolsky-Rosen argument. However, in the framework of the MWI, Bell's argument cannot get off the ground because it requires a predetermined single outcome of a quantum experiment.

Another example of a kind of an action at a distance in a quantum theory with collapse is the *interaction-free measurement* of Elitzur and Vaidman 1993. Consider a super-sensitive bomb which explodes when *any* single particle arrives at its location. It seems that it is impossible to see this bomb, because any photon that arrives at the location of the bomb will cause an explosion. Nevertheless, using the Elitzur and Vaidman method, it is possible, at least sometimes, to find the location of the bomb without exploding it. In the case of success, a paradoxical situation arises: we obtain information about some region of space without any particle being there. Indeed, we know that no particle was in the region of the bomb because there was no explosion. The paradox disappears in the framework of the MWI. The situation is paradoxical because it contradicts physical intuition: the bomb causes an observable change in a remote region without sending or reflecting any particle. Physics is the theory of the Universe and therefore the paradox is real if this story is correct in the whole physical Universe. But it is not. There was no photon in the region of the bomb in a particular world, but there are other worlds in which a photon reaches the bomb and causes it to explode. Since the Universe incorporates all the worlds, it is not true that in the Universe no photon arrived at the location of the bomb. It is not surprising that our physical intuition leads to a paradox when we limit ourselves to a particular world: physical laws are applicable when applied to the physical universe that incorporates all of the worlds.

The MWI is not the most accepted interpretation of quantum theory among physicists, but it is becoming increasingly popular (see Tegmark 1998). The strongest proponents of the MWI can be found in the communities of quantum cosmology and quantum computing. In quantum cosmology it makes it possible to discuss the whole Universe avoiding the difficulty of the standard interpretation which requires an external observer. In quantum computing, the key issue is the parallel processing performed on the same computer; this is very similar to the basic picture of the MWI.[9]

Many physicists and philosophers believe that the most serious weakness of the MWI (and especially of its version presented here) is that it "gives up trying to explain things". In the words of Steane 1999, "It is no use to say that the [Schrödinger] cat is 'really' both alive and dead when every experimental test yields unambiguously the result that the cat is *either* alive *or* dead." (Steane dismisses the interference experiment which can reveal the presence of the superposition as unfeasible.) Indeed, if there is nothing in physics except the wave-function of the Universe, evolving according to the Schrödinger equation, then there are questions answering which requires help by other sciences. However, the advantage of the MWI is that it allows us to view quantum mechanics as a complete and consistent physical theory which agrees with all experimental results obtained to date.

Everett's Relative-State Formulation of Quantum Mechanics

Everett's relative-state formulation of quantum mechanics is an attempt to solve the measurement problem by dropping the collapse dynamics from the standard von Neumann-Dirac theory of quantum mechanics. The main problem with Everett's theory is that it is not at all clear how it is supposed to work. In particular, while it is clear that he wanted to explain why we get determinate measurement results in the context of his theory, it is unclear how he intended to do this. There have been many attempts to reconstruct Everett's no-collapse theory in order to account for the apparent determinateness of measurement outcomes. These attempts have led to such formulations of quantum mechanics as the many-worlds, many-minds, many-histories, and relative-fact theories. Each of these captures part of what Everett claimed for his theory, but each also encounters problems.

Introduction

Everett formulated his relative-state interpretation of quantum mechanics while he was a graduate student in physics at Princeton University. His doctoral dissertation (1957a) was recommended for publication March 1957 and a paper reporting the results of his dissertation (1957b) was published in July of the

same year. He also published an extended discussion of his relative-state interpretation in the DeWitt and Graham anthology (1973). After graduating from Princeton, Everett worked as a defense analyst. He died in 1982.

Everett's no-collapse formulation of quantum mechanics was a reaction to problems that arise in the standard von Neumann-Dirac collapse theory. Everett's proposal was to drop the collapse postulate from the standard theory, then deduce the empirical predictions of the standard theory as the subjective experiences of observers who are themselves treated as physical systems described by his theory. It is, however, unclear precisely how Everett intended for this to work. Consequently, there have been many, mutually incompatible, attempts at trying to explain what he in fact had in mind. Indeed, it is probably fair to say that most no-collapse interpretations of quantum mechanics have at one time or another been attributed to Everett.

In what follows, I will describe Everett's worry about the standard collapse formulation of quantum mechanics and his proposal for solving the problem as it is presented in his 1957 paper. I will then very briefly describe a few approaches to interpreting Everett's theory.

The Measurement Problem

Everett presented his relative-state formulation of quantum mechanics as a way of avoiding the problems encountered by the standard von Neumann-Dirac theory. The main problem, according to Everett, was that the standard theory required observers always to be treated as *external* to the system described by the theory. One unfortunate consequence of this was that the standard theory could not be used to describe the universe as a whole since the universe is a system containing observers.

In order to understand what Everett was worried about, one must first understand how the standard theory works. The standard von Neumann-Dirac theory is based on the following principles (see von Neumann 1955):

> **1. Representation of States**: The possible physical states of a system *S* are represented by the unit-length vectors in a Hilbert space (which for present purposes one may regard as a vector space with an inner product). The physical state at a time is then represented by a single vector in the Hilbert space.
>
> **2. Representation of Properties**: For each physical property *P* that one might observe of a system *S* there is an operator ***P*** (on the vectors that represent the possible states of *S*) that represents the property (in a way determined by the following principle).
>
> **3. Eigenvalue-Eigenstate Link**: A system *S* determinately has physical property *P* if and only if ***P*** operating on ***S*** (the vector representing *S*'s state) yields ***S***. We say then that *S* is in an eigenstate of ***P*** with eigenvalue 1. *S* determinately does not have property *P* if and only

> if ***P*** operating on ***S*** yields 0.
>
> **4. Dynamics**: **(a)**. If no measurement is made, then a system evolves continuously according to the linear, deterministic Schroedinger dynamics, which depends only on the energy properties of the system. **(b)**. If a measurement is made, then the system instantaneously and randomly jumps to a state where it either determinately has or determinately does not have the property being measured (according to the eigenvalue-eigenstate link). The probability of each possible post-measurement state is determined by the system's initial state.

It is worth noting that according to the eigenvalue-eigenstate link (3) a system would typically neither determinately have nor determinately not have a particular given property (a specific property might be represented by a line in the state space: in order to determinately have the property the state of a system must be parallel to the line, and in order to determinately not have the property the state of a system must be orthogonal to the line, and most state vectors are neither parallel nor orthogonal to any given line). Further, the deterministic dynamics (4a), as we will see below, does nothing to guarantee that a system would either determinately have or determinately not have a particular property when one observes the system to see whether the system has that property. This is why the collapse dynamics (4b) is needed: in the standard theory it is what guarantees that a system will either determinately have or determinately not have a property whenever one observes the system to see whether or not it has the property. This is why the standard theory has two dynamical laws: a random, discontinuous one (4b) that describes what happens when a measurement is made and a deterministic, continuous one (4a) that describes what happens the rest of the time.

But what does it take for an interaction to count as a *measurement*? Unless we know this, the standard theory is at best incomplete, since we do not know when each dynamical law obtains. Moreover, and this is what worried Everett, if we suppose that observers and their measuring devices are constructed from simpler systems that each obey the deterministic dynamics, then the composite systems, the observers and their measuring devices, must evolve in a continuous deterministic way, and nothing like the random, discontinuous evolution described by rule 4b can ever occur. That is, if observers and their measuring devices are understood as being constructed of simpler systems each behaving as quantum mechanics requires (each obeying 4a), then the standard theory is logically inconsistent since it says that together the systems must obey 4b. In order to preserve the consistency of the theory, Everett concluded that the standard theory cannot be used to describe systems that contain observers--it can only be used to describe systems where all observers are *external* to the described system. This restriction on the applicability of the theory was unacceptable. Everett wanted a theory that could be applied to any physical system whatsoever, one that described observers and their measuring devices the same way that it described every other physical system.

Everett's Proposal

In order to solve the standard theory's measurement problem Everett proposed dropping the collapse

dynamics (4b) and taking the resulting theory as providing a complete and accurate description of all physical systems whatsoever. He then intended to *deduce* the statistical predictions of quantum mechanics (the predictions that depend on rule 4b in the standard theory) as the subjective experiences of observers who are themselves treated as ordinary physical systems within the new theory.

This is what Everett says: "We shall be able to introduce into [the relative-state theory] systems which represent observers. Such systems can be conceived as automatically functioning machines (servomechanisms) possessing recording devices (memory) and which are capable of responding to their environment. The behavior of these observers shall always be treated within the framework of wave mechanics. Furthermore, we shall deduce the probabilistic assertions of Process 1 [rule 4b] as *subjective* appearances to such observers, thus placing the theory in correspondence with experience. We are then led to the novel situation in which the formal theory is objectively continuous and causal, while subjectively discontinuous and probabilistic. While this point of view thus shall ultimately justify our use of the statistical assertions of the orthodox view, it enables us to do so in a logically consistent manner, allowing for the existence of other observers." (1973, 9)

Everett's goal then was to show that the memory records of an observer as described by his no-collapse theory would match those predicted by the standard theory with the collapse dynamics. The main problem in understanding what Everett had in mind is in figuring out how this correspondence between the predictions of the two theories was supposed to work.

Suppose that *J* is a good observer who measures the *x*-spin of a spin-1/2 system *S* (spin is a property of fundamental particles and other quantum-mechanical systems; if one specifies a particular axis (like *x* or *z*), then a spin-1/2 system will be found, on measurement, to be either "spin up" or "spin down" with respect to the particular axis). For Everett, being a good *x*-spin observer means that *J* has the following two dispositions (the arrows below represent the time-evolution described by the deterministic dynamics 4a):

1. $|\text{“ready”}\rangle_J\,|\text{x-spin up}\rangle_S \rightarrow |\text{“spin up”}\rangle_J\,|\text{x-spin up}\rangle_S$

2. $|\text{“ready”}\rangle_J\,|\text{x-spin down}\rangle_S \rightarrow |\text{“spin down”}\rangle_J\,|\text{x-spin down}_S\rangle$

J measures a system that is determinately *x*-spin up, then *J* will determinately record "spin up"; and if *J* measures a system that is determinately *x*-spin down, then *J* will determinately record "spin down" (and we assume for simplicity that the object system is not undisturbed).

Now consider what happens when *J* observes the *x*-spin of a system that begins in a *superposition* of *x*-spin eigenstates:

$$a|\text{x-spin up}\rangle_S + b|\text{x-spin down}\rangle_S$$

The initial state of the composite system then is:

$$|\text{“ready”}\rangle_J \, (a|\text{x-spin up}\rangle_S + b|\text{x-spin down}\rangle_S)$$

Given *J*'s two dispositions and the fact that the deterministic dynamics is linear, the state of the composite system after *J*'s *x*-spin measurement will be:

$$a|\text{“spin up”}\rangle_J \, |\text{x-spin up}\rangle_S + b|\text{“spin down”}\rangle_J \, |\text{x-spin down}\rangle_S$$

Let's call this state ***E*** for Everett. Note that on the standard eigenvalue-eigenstate link ***E*** is not a state where *J* determinately records "spin up" neither is it a state where *J* determinately records "spin down". So in what sense is *J*'s record supposed to agree with the empirical prediction made by the standard theory (which predicts that *J* will either end up with the determinate record "spin up" or the determinate record "spin down", with probabilities equal to *a*-squared and *b*-squared respectively)?

Everett confesses that such a post-measurement state is puzzling: "As a result of the interaction the state of the measuring apparatus is no longer capable of independent definition. It can be defined only *relative* to the state of the object system. In other words, there exists only a correlation between the states of the two systems. It seems as if nothing can ever be settled by such a measurement." (1957b, 318)

And he describes the problem he faces: "This indefinite behavior seems to be quite at variance with our observations, since physical objects always appear to us to have definite positions. Can we reconcile this feature of wave mechanical theory built purely on [rule 4a] with experience, or must the theory be abandoned as untenable? In order to answer this question we consider the problem of observation itself within the framework of the theory." (1957b, 318)

Then he describes his solution to the determinate-experience problem: "Let one regard an observer as a subsystem of the composite system: observer + object-system. It is then an inescapable consequence that after the interaction has taken place there will not, generally, exist a single observer state. There will, however, be a superposition of the composite system states, each element of which contains a definite observer state and a definite relative object-system state. Furthermore, as we shall see, *each* of these relative object system states will be, approximately, the eigenstates of the observation corresponding to the value obtained by the observer which is described by the same element of the superposition. Thus, each element of the resulting superposition describes an observer who perceived a definite and generally different result, and to whom it appears that the object-system state has been transformed into the corresponding eigenstate. In this sense the usual assertions of [the collapse dynamics (4b)] appear to hold on a subjective level to each observer described by an element of the superposition. We shall also see that correlation plays an important role in preserving consistency when several observers are present and allowed to interact with one another (to ‘consult’ one another) as well as with other object-systems." (1973, 10)

Everett presents a principle of the fundamental relativity of states: one can say that in state ***E***, *J* recorded "*x*-spin up" relative to *S* being in the *x*-spin up state and that *J* recorded "*x*-spin down" relative to *S* being in the *x*-spin down state. But note that this principle alone does not allow Everett to deduce anything like the experiences predicted by the standard collapse theory. The standard theory predicts that on measurement the quantum-mechanical state of the composite system will collapse to either:

$$|\text{“spin up”}\rangle_J\,|\text{x-spin up}\rangle_S \text{ or } |\text{“spin down”}\rangle_J\,|\text{x-spin down}\rangle_S$$

when a measurement is made, and that there is thus a single, simple matter of fact about which measurement result *J* recorded. On Everett's account it is unclear whether *J* ends up recording one result or the other or somehow both or perhaps neither.

The problem is that there is a gap in Everett's exposition between what he sets out to explain (why observers have precisely the same experiences as predicted by the standard theory) and what he ultimately ends up saying. Since it is unclear exactly how he intends for his theory to explain an observer's (apparently?) determinate measurement records, it is also unclear how he intends to explain why one should expect one's determinate measurement records to exhibit the standard quantum statistics. This gap in Everett's exposition has led to the many mutually incompatible reconstructions of his theory--each can be taken as presenting a different way of explaining how one's records can be determinate (or at least *appear* to be determinate) in a post-measurement state like ***E***.

The Bare Theory

Albert and Loewer's bare theory (Albert and Loewer 1988 and Albert 1992) is arguably the wildest interpretation of Everett's theory around. On this reading, one supposes that Everett intended to drop the collapse dynamics but to keep the standard eigenvalue-eigenstate link.

So how does the bare theory account for *J*'s determinate experience? The short answer is that it doesn't. Rather, on the bare theory, one tries to explain why *J* would *falsely* believe that he has an ordinary determinate measurement record. The trick is to ask the observer not what result he got, but rather whether he got *some* specific determinate result. If the post-measurement state was:

$$|\text{“spin up”}\rangle_J\,|\text{x-spin up}\rangle_S$$

then *J* would report "I got a determinate result, either spin up or spin down." And he would make precisely the same report if he ended up in the post-measurement state:

$$|\text{“spin down”}\rangle_J\,|\text{x-spin down}\rangle_S$$

So, by the linearity of the dynamics, *J* would *falsely* report "I got a determinate result, either spin up or

spin down" when in the state ***E***:

$$a|\text{"spin up"}\rangle_J \; |\text{x-spin up}\rangle_S + b|\text{"spin down"}\rangle_J \; |\text{x-spin down}\rangle_S$$

Thus, one might argue, it would *seem* to *J* that he got a perfectly determinate ordinary measurement result even when he did not (that is, he did not determinately get "spin up" and did not determinately get "spin down").

The idea is to try to account for all of *J*'s beliefs about his determinate experiences by appealing to such *illusions*. Rather than predicting the experiences that we believe that we have, a proponent of the bare theory tells us that we do not have many determinate beliefs at all and then tries to explain why we nonetheless determinately believe that we do.

While one can tell several suggestive stories about the sort of illusions that an observer would experience, there are at least two serious problems with the bare theory. One problem is that the bare theory is not empirically coherent: that is, if the bare theory were true, it would be impossible to ever have empirical evidence for accepting it as true. Another is that if the bare theory were true, one would most likely fail to have any determinate beliefs at all (since on the deterministic dynamics one would almost never expect that the global state was an eigenstate of any particular observer being sentient), which is presumably not the sort of prediction one looks for in a successful physical theory (for more details on how experience is supposed to work in the bare theory and some the problems it encounters see Bub, Clifton, and Monton 1998 and Barrett 1994 and 1998).

Many Worlds

DeWitt's many-worlds interpretation is easily the most popular reading of Everett. On this theory there is one world corresponding to each term in the expansion of ***E*** when written in the preferred basis (there are always many ways one might write the quantum-mechanical state of a system as the sum of vectors in the Hilbert space; in choosing a preferred basis, one chooses a single set of vectors that can be used to represent a state and thus one chooses a single *preferred* way of representing a state as the sum of vectors in the Hilbert space). The theory's preferred basis is chosen so that each term in the expansion of ***E*** describes a world where there is a determinate measurement record. Given the preferred basis (surreptitiously) chosen above, ***E*** describes two worlds: one where *J* (or perhaps better *J1*) determinately records the measurement result "spin up" and another where *J* (or *J2*) determinately records "spin down".

DeWitt and Graham describe their reading of Everett as follows: "[Everett's interpretation of quantum mechanics] denies the existence of a separate classical realm and asserts that it makes sense to talk about a state vector for the whole universe. This state vector never collapses and hence reality as a whole is rigorously deterministic. This reality, which is described *jointly* by the dynamical variables and the state vector, is not the reality we customarily think of, but is a reality composed of many worlds. By virtue of the temporal development of the dynamical variables the state vector decomposes naturally into

orthogonal vectors, reflecting a continual splitting of the universe into a multitude of mutually unobservable but equally real worlds, in each of which every good measurement has yielded a definite result and in most of which the familiar statistical quantum laws hold." (1973, v)

DeWitt admits that this constant splitting of worlds whenever the states of systems become correlated is counterintuitive: "I still recall vividly the shock I experienced on first encountering this multiworld concept. The idea of 10^{100} slightly imperfect copies of oneself all constantly spitting into further copies, which ultimately become unrecognizable, is not easy to reconcile with common sense. Here is schizophrenia with a vengeance." (1973, 161)

But while the theory is counterintuitive, it does (unlike the bare theory) explain why observers end up recording determinate measurement results. In the state described by ***E*** there are two observers each occupying a different world and each with a perfectly determinate measurement record. There are, however, other problems with the many-worlds theory.

A standard complaint is that the theory is ontologically extravagant. One would presumably only ever need one physical world, *our* world, to account for *our* experience. The idea behind postulating the actual existence of a different physical world corresponding to each term in the quantum-mechanical state is that is allows one to explain our determinate experiences while taking the deterministically-evolving quantum-mechanical state to be in some sense a complete and accurate description of the physical facts. But again one might wonder whether the sort of completeness one gets warrants the vast ontology of worlds.

Perhaps more serious, in order to explain our determinate measurement records, the theory requires one to choose a preferred basis so that observers have determinate records (or better, determinate *experiences*) in each term of the quantum-mechanical state as expressed in this basis. The problem is that not just any old preferred basis will do this--indeed, we presumably do not know what basis would make our experiences and beliefs determinate in every world. Indeed, the right preferred basis would presumably depend on such things as our physiology and experimental practice, so even if we did know which one to choose, this choice of a fundamental part of our most basic physical theory (the part that tells us when worlds split) would have to be contingent on accidents of biology and practice. We tend to think that our physical laws are independent of such accidental features of the world.

Another problem concerns the statistical predictions of the theory. The standard collapse theory predicts that *J* will get the result "spin up" with probability *a*-squared and "spin down" with probability *b*-squared in the above experiment. But the many-worlds theory cannot, as it stands, make any statistical predictions concerning an observer's future experiences. Indeed, the question "What is the probability that *J* will record the result ‘spin up’?" is strictly nonsense since one cannot identify which of the two future observers is *J*. The upshot is that one cannot capture the standard probabilistic predictions of quantum mechanics. And the moral is that if one does not have transtemporal identity of observers in a theory, then one cannot assign probabilities to their future experiences.

Many Minds

Everett said that on his formulation of quantum mechanics "the formal theory is objectively continuous and causal, while subjectively discontinuous and probabilistic" (1973, 9). Albert and Loewer (1988) have captured this feature in their many-minds theory by distinguishing between the time-evolution of an observer's physical state, which is continuous and causal, and the evolution of an observer's mental state, which is discontinuous and probabilistic.

Perhaps the oddest thing about this theory is that in order to get the observer's mental state in some way to supervene on his physical state, Albert and Loewer associate with each observer a continuous infinity of minds. The physical state always evolves in the usual deterministic way, but each mind evolves randomly (with probabilities determined by the particular mind's current mental state and the evolution of the global quantum-mechanical state). On the mental dynamics that they describe, one would expect *a*-squared of *J*'s minds to end up associated with the result "spin up" (the first term of ***E***) and *b*-squared of *J*'s minds to end up associated with the result "spin down" (the second term of ***E***). The mental dynamics is also stipulated to be memory preserving.

An advantage of this theory over the many-worlds theory is that there is no *physically* preferred basis. To be sure, one must choose a preferred basis in order to specify the mental dynamics completely (something that Albert and Loewer never completely specify), but as Albert and Loewer point out, this choice has absolutely nothing to do with any physical facts; rather, it can be thought of as part of the description of the relationship between physical and mental states. Another advantage of the many-minds theory is that, unlike the many-worlds theory, it really does make the usual probabilistic predictions for the future experiences of a particular mind (this, of course, requires that one take the minds to have transtemporal identities, which Albert and Loewer do as part of their unabashed commitment to a strong mind-body dualism).

The main problems with the many-minds theory concern its commitment to a strong mind-body dualism and the question of whether the sort of mental supervenience one gets is worth the trouble of postulating a continuous infinity of minds associated with each observer. Concerning the latter, one might well conclude that a *single*-mind theory would be preferable (see Barrett 1995).

Many Histories

Gell-Mann and Hartle (1990) understand Everett's theory as one that describes many, mutually decohering histories. The main difference between this approach and the many-worlds interpretation is that, instead of stipulating a preferred basis, here one relies on the physical interactions between a physical system and its environment (the way in which the quantum-mechanical states become correlated) to effectively choose what physical quantity is determinate at each time for each system.

One problem concerns whether and in what sense environmental interactions can select *a physically*

preferred basis for the entire universe, which is what we presumably need in order to make sense of Everett's formulation. After all, in order to be involved in environmental interactions a system must have an environment, and the universe, by definition, has no environment. Another problem is that it is unclear that the environment-selected determinate quantity at a time is a quantity that would explain *our* determinate measurement records and experience. Proponents who argue for this approach often appeal to biological or evolutionary arguments to justify the assumption that sentient beings must record their beliefs in terms of the environment-selected (or decohering) physical properties (see Gell-Mann and Hartle 1990 and Zurek 1991 for this sort of argument). The short story is that it is not yet clear how the account of our determinate experience is suppose to work when one relies on decoherence to select a preferred basis (see Dowker and Kent 1996 for an extended discussion of some of the problems one encounters in such an approach).

If one allows oneself the luxury of stipulating a preferred basis (a basis where every observer's measurement records are determinate), one can construct a many-histories theory from Albert and Loewer's many-minds theory. One might, for example, take the trajectory of each of an observer's minds to describe the history of a possible physical world. One might then stipulate a measure over the set of all possible histories (trajectories) that would represent the prior probability of each history being *ours*. Note that since such worlds (and everything in them) would have transtemporal identities, unlike the many-worlds theory, there would be no special problem here in talking about probabilities concerning one's future experience--the quantum probabilities in such a theory might naturally be interpreted as *epistemic* probabilities.

Relative Facts

Perhaps the approach closest to the spirit of Everett's relative-state formulation would be simply to deny that there are typically any absolute matters of fact about the properties of physical systems or the records, experiences, and beliefs of observers (see Saunders 1995 and Mermin 1997). In the experiment above, *J* does not end up believing that his result was "spin up", and he does not end up believing that his result was "spin down"; rather, on this sort of theory all facts would be relative. Not relative to a particular world, mind, or history, but relative to each other: here *J* believes that his result was "spin up" *relative to S* being *x*-spin up and *J* believes that his result was "spin down" *relative to S* being *x*-spin down. But, one might ask, what is the state of *S* then? Well, *S* is *x*-spin up *relative to J* believing that his result was "spin up", etc. Again, on this sort of theory there are typically no absolute matters of fact about the properties of individual physical systems.

So how do we account for our determinate experience? On this approach, one simply denies that there is any simple matter of fact concerning what an observer's experience is. Which means, of course, that insofar as one believes that there really is a simple matter of fact about what one's experiences is, the relative-fact theory provides no account of one's experience. Similarly, one cannot make sense of the usual statistical predictions of quantum mechanics insofar as one takes these to be predictions concerning the probability that a particular measurement outcome will in fact occur. Again, there are typically no such simple facts in such a theory.

It has been argued that since there is no simple matter of fact concerning whether a particular event does or does not occur, quantum mechanics (in fact?) concerns only the probabilistic correlations between events. It seems to me, however, that any coherent talk about the probabilistic correlations between events presupposes that there are determinate matters of fact concerning what events occur (otherwise what are the probabilities probabilities *of*?).

Summary

Such are some of the ways of understanding Everett's relative-state formulation of quantum mechanics. It will probably never be entirely clear precisely what Everett himself had in mind, but his goal of trying to make sense of quantum mechanics without the collapse postulate was heroic. And even in light of the problems one faces, puzzling over how one might reconstruct Everett's theory continues to hold promise.

Stanford Encyclopedia of Philosophy
Notes to The Many-Worlds Interpretation of Quantum Mechanics

Notes

1. The mathematical part of the MWI, (i), yields less than mathematical parts of some other theories such as, e.g., Bohmian mechanics. Indeed, our experience is consistent with the MWI, but it does not follow from its mathematical part. The Schrödinger equation itself does not explain why we experience definite results in quantum measurements. In contrast, in the Bohmian mechanics the mathematical part yields almost everything, and the analog of (ii) is very simple: it is the postulate according to which only the "Bohmian positions" (and not the quantum wave) correspond to our experience. The Bohmian positions of all particles yield the familiar picture of the (single) world we are aware of. Thus, philosophically, a theory like the Bohmian mechanics achieves more than the MWI, but at the price of a significant impairment of the physical aspects of the theory, e.g., addition of the non-local dynamics of Bohmian particle positions. However, Wallace (2001a) argues that stripping the experiential content from empty waves in the Bohmian approach has significant philosophical difficulties too.

2. Wallace 2001a points out that the term “superposition of a cat” is a misnomer. I use it as a shortcut for “a superposition of states of elementary particles corresponding to different (classical) states of the cat”.

3. It corresponds to the fact that we are aware of objects like cats, tables, etc. that are well localized and are in a definite state. The position need not and must not be exact: its uncertainty should be small only relative to the precision with which we can measure it and the uncertainty must remain such for a period of time. Therefore, due to the uncertainty principle, it cannot be too small.

4. The quantum state of the world is the normalized projection of the quantum state of the Universe onto the space corresponding to the classical description of the world. It is a product state only for variables which are relevant for the macroscopic description of the objects. There might be some entanglement between weakly coupled variables like nuclear spins belonging to different objects. In order to keep the form of the quantum state of the world (1), the quantum state of such variables should belong to $|\Phi\rangle$.

5. Since there is a strong philosophical denial of a possibility to have a nondichotomic degree of existence, the name is clearly problematic, however, it seems that no other word fits better.

6. An even more severe difficulty of this kind appears in the *consistent-histories approach* considered by Gell-Mann and Hartle as an advanced MWI. Its basic concept, the *probability of a history*, seems to be meaningless since all histories exist. However, Saunders finds this approach useful for the analysis of probability.

7. This postulate is a counterpart of the collapse postulate of standard quantum mechanics according to which, after measurement, the quantum state collapses to a particular branch with probability proportional to its squared amplitude. (See the entry on quantum mechanics.) However, it differs in two aspects. First, it is the parallel of only the second part of the collapse postulate, the Born Rule, and second, it is related only to part (ii) of the MWI, the connection to our experience, and not to the mathematical part of the theory (i).

8. Proponents of the MWI might argue that, in fact, the burden of an experimental proof lies on the opponents of the MWI, because it is they who claim that there is new physics beyond the well tested Schrödinger equation.

9. Steane challenges the claim that a quantum computer performs parallel computations, but this is certainly the most natural interpretation of the operation of the first quantum algorithm which works faster than any classical one, see Experiment 2 in Deutsch (1986).

Identity and Individuality in Quantum Theory

What are the metaphysical implications of quantum physics? One way of approaching this question is to consider the impact of the theory on our understanding of objects as individuals with well defined identity conditions. One view is that quantum theory implies that the fundamental particles of physics cannot be regarded as individual objects in this sense. Such a view has motivated the development of non-standard formal systems which are appropriate for representing such non-individual objects. However, it has also been argued that quantum physics is in fact compatible with a metaphysics of individual objects. Nevertheless, such objects are indistinguishable in a sense which leads to the violation of Leibniz's famous Principle of the Identity of Indiscernibles. Finally, this underdetermination of the metaphysics of individuality by the physics has important implications for the realism-antirealism debate.

Introduction

It is typically held that chairs, trees, rocks, people and many of the so-called ‘everyday’ objects we encounter can be regarded as individuals; the issue, then, is how this individuality is to be understood, or what constitutes the ‘principle’ of individuality. This is an issue which has a very long history in philosophy. A number of approaches to it can be broadly delineated.

We might begin by noting that a tree and rock, say, can be *distinguished* in terms of their different

properties. We might then go further and insist that this also forms the basis for ascribing *individuality* to them. Even two apparently very similar objects, such as two coins of the same denomination or so-called identical twins, will display *some* differences in their properties - a scratch here, a scar there, and so on. On this account such differences are sufficient to both distinguish and individuate the objects. This forms the basis of the so-called ‘bundle’ view of individuality, according to which an individual is *nothing but* a bundle or properties. On this view, no two individuals can be absolutely indistinguishable, or indiscernible, in the sense of possessing *exactly* the same set of properties. This last claim has been expressed as the Principle of Identity of Indiscernibles and we shall return to it below.

However, this approach has been criticised on the grounds (among others) that we can surely *conceive* of two absolutely indistinguishable objects: thinking of Star Trek, we could imagine a replicator device which precisely reproduces an object, such as a coin or even a person, giving two such objects with exactly the same set of properties. Not quite, one might respond, since these two objects do not and indeed cannot exist at the same place at the same time; that is, they do not possess the same spatio-temporal properties. In terms of *these* properties, then, the objects can still be distinguished and hence regarded as different individuals. Clearly, then, this approach to the issue of individuality must be underpinned by the assumption that individual objects are *impenetrable*.

A more thorough-going criticism of this property based approach to individuality insists that it conflates *epistemological* issues concerning how we distinguish objects, with *ontological* issues concerning the metaphysical basis of individuality. Thus, it is argued, to talk of distinguishability requires at least two objects but we can imagine a universe in which there exists only one. In such a situation, it is claimed, it would be inappropriate to say that the object is distinguishable but not that it is an individual. Although we do not actually find ourselves in such situations, of course, still, it is insisted, distinguishability and individuality should be kept *conceptually* distinct.

If this line of argument is accepted, then the principle of individuality must be sought in something over and above the properties of an object. One candidate is the notion of substance, in which properties are taken to inhere in some way. Locke famously described substance as a ‘something, we know not what’, since to describe it we would have to talk of its properties but bare substance, by its very nature, has no properties itself.

Alternatively, the individuality of an object has been expressed in terms of its ‘haecceity’ or ‘primitive thisness’ (Adams 1979). As the name suggests, this is taken to be the primitive basis of individuality, which cannot be analysed further. However, it has also been identified with the notion of self-identity, understood as a relational property (Adams *ibid*.) and expressed more formally as ‘a=a’. Each individual is understood to be identical to itself. This may seem like a form of the property based approach we started with, but self-identity is a rather peculiar kind of property.

This is just a sketch of some of the various positions that have been adopted. There has been considerable debate over which of them applies to the everyday objects mentioned above. But at least it is generally agreed that such objects should be regarded as individuals to begin with. What about the fundamental objects posited by current physical theories, such as electrons, protons, neutrons etc.? Can these be

regarded as individuals? One response is that they cannot, since they behave very differently in aggregates from 'classical' individuals.

Quantum Non-Individuality

The argument for the above conclusion -- that the fundamental objects of physics cannot be regarded as individuals -- can be summed up as follows: First of all, both 'classical' and 'quantal' objects of the same kind (e.g. electrons) can be regarded as indistinguishable in the sense of possessing the same intrinsic properties, such as rest mass, charge, spin etc. Consider now the distribution of two such indistinguishable particles over two boxes, or two states in general:

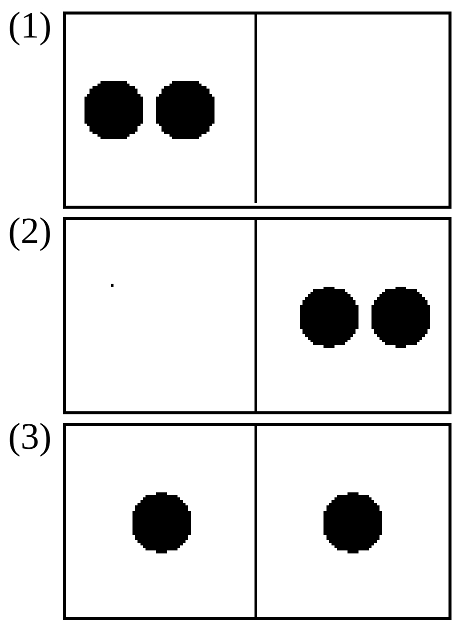

Figure 1

In classical physics, (3) is given a weight of twice that of (1) or (2), corresponding to the two ways the former can be achieved by permuting the particles. This gives us four combinations or complexions in total and hence we can conclude that the probability of finding one particle in each state, for example, is 1/2. (Note that it is assumed that none of the four combinations is regarded as privileged in any way, so each is just as likely to occur.) This is an example of the well-known 'Maxwell-Boltzmann' statistics to which, it is claimed, thermodynamics was reduced at the turn of the century.

In quantum statistical mechanics, however, there are two 'standard' possibilities: one for which there are three possible arrangements in the above situation (both particles in one box, both particles in the other, and one in each box), giving 'Bose-Einstein' statistics; and one for which there is only one arrangement (one particle in each box), giving 'Fermi-Dirac' statistics. Setting aside the differences between these two kinds of quantum statistics, the important point for the present discussion is that in the quantum case, a permutation of the particles is not regarded as giving rise to a new arrangement. This result lies at the very heart of quantum physics and putting things slightly more formally, it is expressed by the so-called

'Indistinguishability Postulate':

> If a particle permutation P is applied to any state function for an assembly of particles, then there is no way of distinguishing the resulting permuted state function from the original unpermuted one by means of any observation at any time.

(The state function of quantum mechanics determines the probability of measurement results. Hence what the Indistinguishability Postulate expresses is that a particle permutation does not lead to any difference in the probabilities for measurement outcomes.)

The argument then continues as follows: that a permutation of the particles is counted as giving a different arrangement in classical statistical mechanics implies that, although they are indistinguishable, such particles can be regarded as individuals (indeed, Boltzmann himself made this explicit in the first axiom of his 'Lectures on Mechanics'). Since this individuality resides in something over and above the intrinsic properties of the particles in terms of which they can be regarded as indistinguishable, it has been called 'Transcendental Individuality' by Post (1963). This notion can be cashed out in various well-known ways, as indicated in the Introduction above: in terms of some kind of underlying Lockean substance (French 1989a), for example, or in terms of primitive thisness (Teller 1995). More generally, one might approach it in modal fashion, through the doctrine of haecceitism: this asserts that two possible worlds may describe some individual in qualitatively the same way (that is, as possessing the same set of properties), yet represent that individual differently by ascribing a different haecceity or thisness in each world, or more generally, by ascribing some non-qualitative aspect to the individual. (Lewis 1986; Huggett 1999).

Conversely, it is argued, if such permutations are not counted in quantum statistics, it follows that quantal particles cannot be regarded as individuals in any of these senses (Post op. cit.). In other words, quantal objects are very different from most everyday objects in that they are 'non-individuals', in some sense.

This radical metaphysical conclusion can be traced back to the very earliest reflections on the foundations of quantum physics. As Weyl put it in his classic text:

> ... the possibility that one of the identical twins Mike and Ike is in the quantum state E1 and the other in the quantum state E2 does not include two differentiable cases which are permuted on permuting Mike and Ike; it is impossible for either of these individuals to retain his identity so that one of them will always be able to say 'I'm Mike' and the other 'I'm Ike.' Even in principle one cannot demand an alibi of an electron! (Weyl 1931)

Recalling the discussion sketched in the Introduction, if we were to create a twin using some kind of Star trek replicator, say, then in the classical domain such a twin could insist that 'I'm here and she's there' or, more generally, 'I'm in this state and she's in that one' and 'swapping us over makes a difference'. In the classical domain each (indistinguishable) twin has a metaphysical 'alibi' grounded in their individuality. Weyl's point is that in quantum mechanics, they do not.

Quantum Individuality

This conclusion -- that quantal objects are not individuals -- is not the whole story, however. First of all, the contrast between classical and quantum physics with regard to individuality and non-individuality is not as straightforward as it might seem. As already indicated, the above account involving permutations of particles in boxes appears to fit nicely with an understanding of individuality in terms of Lockean substance or primitive thisness. However, one can give an alternative field-theoretic account in which particles are represented as dichotomic ‘Yes/No’ fields: with such a field, the field amplitude is simply ‘Yes’ at location x if the ‘particle’ is present at x and ‘No’ if it is not (Redhead 1983). On this account, individuality is conferred via spatio-temporal location together with the assumption of impenetrability mentioned in the Introduction. Thus the above account of particle individuality in terms of either Lockean substance or primitive thisness is not necessary for classical statistical mechanics (French 1989a).

The particles-and-boxes picture above corresponds to the physicists' multidimensional ‘phase space’, which describes which individuals have which properties, whereas the field- theoretic representation corresponds to ‘distribution space’, which simply describes which properties are instantiated in what numbers. Huggett has pointed out that the former supports haecceitism, whereas the latter does not and, furthermore,that the empirical evidence provides no basis for choosing between these two spaces (Huggett 1999). Thus the claim that classical statistical mechanics is wedded to haecceitism also becomes suspect.

Secondly, the above argument from permutations can be considered from a radically different perspective. In the classical case the situations with one particle in each box are given a weight of ‘2’ in the counting of possible arrangements. In the case of quantum statistics this situation is given a weight of ‘1’. With this weighting, there are two possible statistics, however: Bose-Einstein, corresponding to a symmetric state function for the assembly of particles and Fermi-Dirac, corresponding to an anti-symmetric state function. Given the Indistinguishability Postulate, it can be shown that symmetric state functions will always remain symmetric and anti-symmetric always anti-symmetric. Thus, if the initial condition is imposed that the state of the system is either symmetric or anti-symmetric, then only one of the two possibilities -- Bose-Einstein or Fermi-Dirac -- is ever available to the system, and this explains why the weighting assigned to ‘one particle in each state’ is half the classical value. This gives us an alternative way of understanding the difference between classical and quantum statistics, not in terms of the lack of individuality of the particles, but rather in terms of which states are accessible to them (French and Redhead 1988; French 1989a). In other words, the implication of the different ‘counting’ in quantum statistics is not that the particles are non-individuals in some sense, but that there are different sets of states available to them, compared to the classical case. On this view, the particles can still be regarded as individuals - however their individuality is to be understood metaphysically.

Both of these perspectives raise interesting metaphysical issues. Let us consider, first, Leibniz's famous Principle of the Identity of Indiscernibles in the context of the particles- as-individuals package.

Quantum Physics and the Identity of Indiscernibles

It should be emphasised, first of all, that quantal particles are indistinguishable in a much stronger sense than classical particles. It is not just that two or more electrons, say, possess all intrinsic properties in common but that - on the standard understanding - no measurement whatsoever could in principle determine which one is which. If the non-intrinsic, state-dependent properties are identified with all the monadic or relational properties which can be expressed in terms of physical magnitudes associated with self-adjoint operators that can be defined for the particles, then it can be shown that two bosons or two fermions in a joint symmetric or anti-symmetric state respectively have the same monadic properties and the same relational properties one to another (French and Redhead 1988; see also Butterfield 1993). This has immediate implications for Leibniz's Principle of the Identity of Indiscernibles which, expressed crudely, insists that two things which are indiscernible, must be, in fact, identical.

Setting aside the historical issue of Leibniz's own attitude, supporters of the Principle have tended to retreat from the claim that it is necessary, to the view that it is at least contingently true. There is the further issue as to how the Principle should be characterised and, in particular, there is the question of what properties are to be included within the scope of those relevant to judgments of indiscernibility. Excluding the peculiar property of self-identity, three forms of the Principle can be distinguished according to the properties involved: the weakest form, PII(1), states that it is not possible for two individuals to possess all properties and relations in common; the next strongest, PII(2), excludes spatio-temporal properties from this description; and the strongest form, PII(3), includes only monadic, non-relational properties. Thus, for example, PII(3) is the claim that no two individuals can possess all the same monadic properties (a strong claim indeed, although it is one way of understanding Leibniz's own view).

In fact, PII(2) and PII(3) are clearly violated in classical physics, where distinct particles of the same kind are typically regarded as indistinguishable in the sense of possessing all intrinsic properties in common and such properties are regarded as non-relational in general and non-spatio-temporal in particular. (Of course, Leibniz himself would not have been perturbed by this result, since he took the Principle of Identity of Indiscernibles to ultimately apply only to ‘monads’, which were the fundamental entities of his ontology. Physical objects such as particles were regarded by him as merely ‘well founded phenomena’.) However, PII(1) is not violated classically, since classical statistical mechanics typically assumes that such particles are impenetrable, in precisely the sense that their spatio-temporal trajectories cannot overlap. Hence they can be individuated via their spatio-temporal properties, as indicated above.

The situation appears to be very different in quantum mechanics, however. If the particles are taken to possess both their intrinsic and state-dependent properties in common, as suggested above, then there is a sense in which even the weakest form of the Principle, PII(1), fails (Cortes 1976; Teller 1983; French 1989b; for an alternative view, see van Fraassen 1985 and 1991). On this understanding, the Principle of Identity of Indiscernibles is actually false. Hence it cannot be used to effectively guarantee individuation via the state-dependent properties by analogy with the classical case. If one wishes to maintain that quantum particles are individuals, then their individuality will have to be taken as conferred by Lockean

substance, primitive thisness or, in general, some form of non-qualitative haecceistic difference.

Of course, if the particles are taken to be non-individuals, in some still to be articulated sense, then the issue is simply obviated and Leibniz's Principle does not apply. However, what sense can we make of the notion of ‘non-individuality’?

Non-individuality and self-identity

Let us recall Weyl's statement that one can't ask alibis of electrons. Dalla Chiara and Toraldo di Francia refer to quantum physics as ‘the land of anonymity’, in the sense that, on this view,the particles cannot be uniquely labelled (1993). They ask, then, how can we talk about what happens in such a land? Their suggestion is that quantal particles can be regarded as ‘intensional-like entities’, where the intensions are represented by conjunctions of intrinsic properties. The extension of the natural kind, ‘electron’, say, is then given by the collection of indistinguishable elements, or a ‘quaset’. Quaset theory then gives the possibility of a semantics for quantum particles without alibis (ibid.).

Alternatively, but relatedly, non-individuality can be understood in terms of a loss of self- identity. This suggestion can be found most prominently in the philosophical reflections of Born, Schrödinger, Hesse and Post (Born 1943; Schrödinger 1952; Hesse 1963; Post 1963). It is immediately and clearly problematic, however: how can we have objects that are not self-identical? Such self-identity seems bound up with the very notion of an object in the sense that it is an essential part of what it is to be an object. This intuition is summed up in the Quinean slogan, ‘no entity without identity’ (Quine 1969), with all its attendant consequences regarding reference etc.

However, Barcan Marcus has offered an alternative perspective, insisting on ‘No identity without entity.’ (Marcus 1993) and arguing that although ‘... all terms may "refer" to objects... not all objects are things, where a thing is at least that about which it is appropriate to assert the identity relation.’ (ibid., p. 25) Object-reference then becomes a wider notion than thing-reference. Within such a framework, we can then begin to get a formal grip on the notion of objects which are not self-identical through so-called ‘Schrödinger logics’, introduced by da Costa (da Costa and Krause 1994) These are many-sorted logics in which the expression x = y is not a well-formed formula in general; it is where x and y are one sort of term, but not for the other sort corresponding to quantum objects. A semantics for such logics can be given in terms of ‘quasi-sets’ (da Costa and Krause 1997). The motivation behind such developments is the idea that collections of quantum objects cannot be considered as sets in the usual Cantorian sense of ‘... collections into a whole of definite, distinct objects of our intuition or of our thought.’ (Cantor 1955, p. 85.). Quasi-set theory incorporates two kinds of basic posits or ‘Urelemente’: m-atoms, whose intended interpretation are the quantal objects and M-atoms, which stand for the ‘everyday’ objects, and which fall within the remit of classical set theory with Ur- elements. Quasi-sets are then the collections obtained by applying the usual Zermelo- Fraenkel framework plus Urelement ZFU-like axioms to a basic domain composed of m- atoms, M-atoms and aggregates of them (Krause 1992; for a comparison of qua-set theory with quasi-set theory, see Dalla Chiara, Giuntini and Krause 1998).

These developments supply the beginnings of a categorial framework for quantum ‘non- individuality’ which can be extended into the foundations of Quantum Field Theory, where it has been argued, one has non-individual ‘quanta’ (Teller 1995). A form of quasi-set theory may offer one way of formally capturing this notion (French and Krause 1999).

Metaphysical Underdetermination

We now appear to have an interesting situation. Quantum mechanics is compatible with two distinct metaphysical ‘packages’, one in which the particles are regarded as individuals and one in which they are not. Thus, we have a form of ‘underdetermination’ of the metaphysics by the physics (see van Fraassen 1985 and 1991; French 1989a; Huggett 1997; Balousek, forthcoming). This has implications for the broader issue of realism within the philosophy of science. If asked to spell out her beliefs, the realist will point to currently accepted fundamental physics, such as quantum mechanics, and insist that the world is, at least approximately, however the physics says it is. Of course, there are the well-known problems of ontological change (giving rise to the so-called pessimistic meta-induction) and underdetermination of theories by the data. However, the above underdetermination of metaphysical packages seems to pose an even more fundamental problem, as the physics involved is well entrenched and the difference in the metaphysics seemingly as wide as it could be. These packages support dramatically different world-views: one in which quantal particles are individuals and one in which they are not. The realist must then face the question: which package corresponds to the world? The physics itself can offer no help whatsoever and any justification for choosing one package over the other which appeals to metaphysical considerations, for example, runs the risk of drastically watering down the science in scientific realism.

Faced with this situation, the anti-realist may conclude ‘so much for metaphysics’ and insist that all that theories can tell us is how the world *could* be (van Fraassen 1991). A possible alternative would be for realism to retreat from a metaphysics of objects entirely and develop an ontology of structure compatible with the physics (Ladyman 1998). An early attempt to do this in the quantum context can be seen in the work of Cassirer who noted the implications for our notion of individual objects and concluded that particles were describable only as ‘"points of intersection" of certain relations’ (1937, p. 180) However, the neo-Kantian elements in Cassirer's structuralist approach may lead one to wonder whether this suggestion actually takes us too far from realism.

Alternatively, it has been argued that the underdetermination can in fact be ‘broken’ because the package of particles-as-non-individuals meshes better with quantum field theory (QFT) where, it is claimed, talk of individuals is avoided from the word go (Post, op. cit.; Redhead and Teller 1991 and 1992; Teller 1995). The central argument for such a claim focuses on the above view that particles may be seen as individuals subject to restrictions on the sets of states they may occupy. The states that are inaccessible to the particles of a particular kind can be seen as corresponding to just so much ‘surplus structure’. In particular, if the view of particles as individuals is adopted, then it is entirely mysterious as to why a particular sub-set of these inaccessible, surplus states, namely those that are non-symmetric, are not actually realised. Applying the general methodological principle that a theory which does not contain such surplus structure is to be preferred over one that does, Redhead and Teller conclude that we have

grounds for preferring the non-individuals approach and the afore-mentioned mystery simply does not arise.

This line of argument has been criticised by Huggett on the grounds that the apparent mystery is a mere fabrication: the inaccessible non-symmetric states can be ruled out as simply not physically possible (Huggett 1995). The surplus structure, then, is a consequence of the representation chosen and has no further metaphysical significance. At issue here is the claim that a theory should tell us why a state of affairs is not possible. Consider the possible state of affairs in which a cold cup of tea spontaneously starts to boil. Statistical mechanics can explain why we never observe such a possibility, whereas the quantum-particles-as-individuals view cannot explain why we never observe non- symmetric states (Teller 1998).

However, the analogy is problematic. Statistical mechanics does not say that the above situation never occurs but only that the probability of its occurrence is extremely low. The question then reduces to that of ‘why is this probability so low?’ The answer to that is typically given in terms of the very low number of states corresponding to the tea boiling compared to the vast number of states for which it remains cold. Why, then, this disparity in the number of accessible states? Or, equivalently, why do we find ourselves in situations in which entropy increases? One answer takes us back to the initial conditions of the big bang. Perhaps a similar line can be taken in the case of quantum statistics. Why do we never observe non-symmetric states? Because that is the way the universe is and we should not expect quantum mechanics alone to have to explain why certain initial conditions obtain and not others. Here we recall that the symmetry of the Hamiltonian ensures that if a particle is in a state of a particular symmetry to begin with, it will remain in states of that symmetry. Hence, if non-symmetric states do not feature in the initial conditions which held at the beginning of the universe, they will remain forever inaccessible to the particles. The issue then turns on different views of the significance of the above ‘surplus structure’. (A detailed critique of the presuppositions of the Redhead and Teller argument can also be found in Balousek, forthcoming.)

Furthermore, even if we accept the methodological principle of ‘the less surplus structure the better’, it is not clear that QFT understood in terms of non-individual ‘quanta’ offers a significant advantage in this respect. Indeed, it has been argued that the formalism of QFT is compatible with the alternative package of metaphysically individual particles. van Fraassen has pressed this claim (1991), drawing on de Muynck's construction of state spaces for quantum field theory which involve labelled particles (1975). However, Butterfield has suggested that the existence of states that are superpositions of particle number, within QFT, undermines the equivalence (1993). Nevertheless, Huggett insists, in this case the undermining is empirical, rather than methodological (Huggett 1995). When the number is constant, it is the states for arbitrary numbers of particles which are so much surplus structure and now, if the methodological argument is applied, it is the individuals package which is to be preferred.

The exploration of these concerns in the context of quantum field theory has only just begun (see also Auyang 1995) and a collection of historical and philosophical reflections on relevant issues can be found in Cao (1999).

A further approach to this underdetermination is to reject both packages and seek a third way. Thus Lavine has suggested that quantum particles can be regarded as the smallest possible amounts of 'stuff' and, crucially, that a multi-particle state represents a further amount of stuff such that it does not contain proper parts (1991). Such a view, he claims, avoids the metaphysically problematic aspects of both the individuals and non-individuals packages. Of course, there are then the issues of the metaphysics and logic of 'stuff', but, he insists, these are familiar and not peculiar to quantum mechanics. One such issue concerns the nature of 'stuff': is it our familiar primitive substance? Substance as a fundamental metaphysical primitive faces acute difficulties and it has been suggested that it should be dropped in favour of an analysis of individual objects in terms of 'tropes', where a trope is an individual instance of a property or a relation. If this notion is broadened to include an individual whose existence depends on that of another individual which is not a part of it then, it is claimed, this notion may be flexible enough to accommodate quantum physics (Simons 1998). Another issue concerns the manner in which 'stuff' combines: how do we go from the amounts of stuff represented by two independent photons, to the amount represented by a joint two-photon state? The analogies Lavine gives are well known: drops of water, money in the bank, bumps on a rope (Teller 1983; Hesse 1963). Of course, these may also be appropriated by the non-individual objects view but, more significantly, they are suggestive of a field-theoretic approach in which the 'stuff' in question is the quantum field.

Here we return to issues concerning the metaphysics of quantum field theory and it is worth pointing out that underdetermination may arise here too. In classical physics we are faced with a choice between the view of field quantities as properties of space-time points and the view of the field as a kind of substance or stuff. In the case of quantum field theory, the field quantities are not well-defined at space-time points (because of difficulties in defining exact locational states in quantum field theory). Instead they are regarded as 'smeared' over space-time regions (see Teller 1999). This does not remove the possibility of underdetermination, of course, as it now arises between the understanding of the quantum field in terms of properties of space-time *regions* and the understanding of the field in terms of substance. However, further issues then arise with regard to the nature of space-time itself. Conceiving of a field in terms of a set of properties meshes comfortably with the approach that takes space-time to be a kind of substance or 'stuff'. This approach faces well known difficulties in the context of modern physics (see, for example, Earman 1989). Unfortunately, the above properties based account of a field is incompatible with the alternative approach to space-time, which takes it to be merely a system of relations (such as contiguity) between physical bodies: if the field quantities are properties of space-time regions and the latter are understood, ultimately, to be reducible to relations between physical objects, where the latter are conceived of in field-theoretic terms, then a circularity appears to arise. If General Relativity is understood as supporting this 'relationist' account of space-time, then we appear to have a significant incompatibility between these two fundamental theories of modern physics (Rovelli 1999). Perhaps, as Stachel has suggested, this incompatibility can be traced back to the sharp, *metaphysical* distinction between *things* and *relations* between things (Stachel 1999). A broadly 'structural realist' approach might offer a way around this incompatibility by regarding both space-time and the quantum field in structural terms (see Auyang 1995).

Such an approach can also be articulated within the particles picture. Returning to the more developed views of both Weyl and Wigner, particles can be understood as ontologically constituted, in group

theoretical terms, as sets of invariants, such as rest mass, charge or spin, for example (Castellani 1998a). From this perspective, both the individuality and non-individuality packages get off on the wrong feet, as it were, by taking it that there is something - transcendental individuality - that is present in the one case and ‘lost’ in the other. The suggestion that particles might be seen as aspects of ‘world structure’ again fits nicely with structural realism. However, in the absence of further metaphysical explication of the notion of structure itself, it is not yet clear whether or not such an approach collapses into another form of the well known conception of objects as bundles of properties, mentioned in the Introduction.

Excellent overviews of the above and related issues can be found in Huggett (1997) and Castellani (1998b).

The Identity of Indiscernibles

The Identity of Indiscernibles is a principle of analytic ontology first explicitly formulated by Wilhelm Gottfried Leibniz in his *Discourse on Metaphysics*, Section 9 (Loemker 1969: 308). It states that no two distinct substances exactly resemble each other. This is often referred to as 'Leibniz's Law' and is typically understood to mean that no two objects have exactly the same properties. The Identity of Indiscernibles is of interest because it raises questions about the factors which individuate qualitatively identical objects. Recent work on the interpretation of quantum mechanics suggests that the principle fails in the quantum domain.

Formulating the Principle

The Identity of Indiscernibles (hereafter called the Principle) is usually formulated as follows: if, for every property *F*, object *x* has *F* if and only if object *y* has *F*, then *x* is identical to *y*. Or in the notation of symbolic logic:

$$(\forall F)(Fx \leftrightarrow Fy) \rightarrow x=y.$$

This formulation of the Principle is equivalent to the Dissimilarity of the Diverse as McTaggart called it, namely: if *x* and *y* are distinct then there is at least one property that *x* has and *y* does not, or vice versa.

The converse of the Principle, $x=y \rightarrow (\forall F)(Fx \leftrightarrow Fy)$, is called the Indiscernibility of Identicals. Sometimes the conjunction of both principles, rather than the Principle by itself, is known as Leibniz's

Law.

Thus formulated, the actual truth of the Principle seems unproblematic for medium-sized objects, such as rocks and trees, for they are complex enough to have distinguishing or individuating features, and hence may always be distinguished by some slight physical difference. But fundamental principles are widely held to be non-contingent. We might require, therefore, that the Principle should hold even for hypothetical cases of qualitatively identical medium sized objects (e.g., clones which, contrary to fact, really are molecule for molecule replicas). In that case, we shall need to distinguish such objects by their spatial relations to other objects (e.g., where they are on the surface of the planet). In that case the Principle is consistent with a universe in which there are three qualitatively identical spheres A, B, and C where B and C are 3 units apart, C and A are 4 units apart and A and B are 5 units apart. In such a universe, A's being 5 units from B distinguishes it from C, and A's being 4 units from C distinguishes it from B. The Principle often gets called into question, however, when we consider qualitatively identical objects in a symmetrical universe. Consider, for instance, a perfectly symmetrical universe consisting solely of three qualitatively identical spheres, A, B and C, each of which is the same distance away from the others. In this case there seems to be no property which distinguishes any of the spheres from any of the others. Some would defend the Principle even in this case by claiming that there are properties such as *being that very object A.* Call such a property a *thisness* or *haecceity*.

The possibility of resorting to thisnesses might make us query whether the usual formulation of the Principle is correct. For as initially stated the Principle told us that no two substances exactly resemble each other. Yet if A and B otherwise exactly resemble each other then, on a common intuition, the fact that A has the property *being identical to A* while B has the distinct property *being identical to B* cannot result in a respect in which A and B fail to resemble each other.

Rather than argue about these intuitions and hence argue as to which is the correct formulation of the Principle we may distinguish different formulations, and then discuss which, if any, of these are correct. To that end a distinction is commonly made between *intrinsic* and *extrinsic* properties. Here it might initially seem that extrinsic properties are those analysed in terms of some relation. But this is not correct. For the property *being composed of two concentric spheres* is intrinsic. For present purposes it suffices to have an intuitive grasp of the intrinsic/extrinsic distinction.

Another useful distinction is between the *pure* and the *impure*. A property is said to be *impure* if it is analysed in terms of a relation with some particular substance (e.g., *being within a light year of the Sun*). Otherwise it is *pure* (e.g., *being within a light year of a star*). Those two examples are both of extrinsic properties, but some intrinsic properties are impure, (e.g., *being composed of the Earth and the Moon*). According to my definitions all non-relational properties are pure.

Armed with these distinction we may ask which properties are to be considered when we formulate the Principle. Of the various possibilities two seem to be of greatest interest. The *Strong* version of the Principle restricts it to pure intrinsic properties, the *Weak* to pure properties. If we allow impure properties the Principle will be even weaker and, I would say, trivialised. For instance in the three sphere example the impure properties *being 2 units from B* and *being 2 units from C* are possessed by A and

only A, yet intuitively they do not prevent exact resemblance between A B and C. (For a different classification of principles, see Swinburne (1995.))

Suppose we take identity to be a relation and analyse thisnesses as relational properties, (So A's thisness is analysed as *being identical to A*). Then thisnesses will be impure but intrinsic. In that case the world consisting of the three qualitatively identical spheres distance apart 3, 4 and 5 units satisfies the Weak but not the Strong Principle. And the world with the three spheres each 2 units distance from the others satisfies neither version.

A further distinction is whether the Principle concerns all items in the ontology or it is restricted to just the category of *substances* (ie things which have properties and/or relations but are not themselves properties and/or relations.) It is usually thus restricted although Swinburne (1995) does consider, and defend, its application to such abstract objects as integers, times and places, without explicitly treating these as substance.

Ontological Implications

Most formulations of the Principle carry a prima facie commitment to an ontology of properties, but nominalists of various kinds should have little difficulty in providing suitable paraphrases to avoid this commitment. Most interesting in this context is the way the Principle can be stated in terms of resemblance without any mention of properties at all. Thus the Strong Principle might be formulated as denying that distinct substances ever exactly resemble, and the Weak Principle as denying that distinct states of affairs ever exactly resemble.

Russell (e.g., 1940, Chapter 6) held that a substance just is a bundle of universals themselves related by a special relation between properties, known as *compresence*. If the universals in question are taken to be intrinsic properties, then Russell's theory implies the Strong Principle.(At least it *seems* to imply it, but see O'Leary-Hawthorne 1995 and Zimmerman 1997.) And if the status of substances is non-contingent then it implies the necessity of the Strong Principle. This is important because the most vulnerable version is clearly the Strong when it is held to be non-contingent. (See also Armstrong 1989, Chapter 4.)

Recent arguments for and against the Principle

(i) The Principle appeals to empiricists. For how could we ever have empirical evidence for two indiscernible items? If we did, empiricists might say, then they would have to be differently related to us. So unless we ourselves have exact replicas, which is implausible, empirically distinguishable objects must have different pure properties. From this and the empiricist premiss that there are no things which are not empirically distinguishable, we would conclude that the Weak Principle holds. Presumably the premiss would not be proposed as anything more than contingently true. For there are possible situations in which there would be theoretical reasons for believing in indiscernible items as a consequence of a theory which best explains the empirical data. Thus we might come to hold a theory of the origins of the

physical universe which had large amounts of empirical support, and which implied that, in addition to our enormously complicated universe, various simpler ones had been generated. For some of the simplest universes this theory might imply that there were exact replicas. In that case the Weak Principle would fail.

(ii) If we ignore quantum mechanics, we might well conclude that not merely the Weak Principle is contingently correct but even the Strong Principle. For unless we take space to be discrete, the classical mechanical situation would seem to be summed up by the Poincaré recurrence theorem which tells us that typically we get arbitrarily close to an exact repetition, but never get to one. (See Earman 1986, p. 130.)

(iii) Concerning the Weak Principle there has been an interesting development of a line of argument due to Black (1952) and Ayer (1954) in which it is proposed that there could be exact symmetry in the universe, even though, once again, the probability of this occurring is infinitesimal. In Black's example it is suggested that there could be a universe containing nothing but two exactly resembling spheres. In such a completely symmetrical universe the two spheres would be indiscernible. Against this has been noted, e.g., Hacking (1975), that such a completely symmetrical situation of two spheres could be re-interpreted as one sphere in a non-Euclidean space. So what might be described as a journey from one sphere to a qualitatively identical one 2 units apart could be redescribed as a journey around space back to the very same sphere. Quite generally it might be said that we may always redescribe apparent counter-examples to the Weak Principle so that qualitatively identical objects symmetrically situated are interpreted as the very same object.

A rejoinder to this is the continuity argument, essentially due to Adams (1979). It is granted that almost perfect symmetry is possible. For there could be a space with nothing in it but two distinct spheres differing very slightly. Black's example of qualitatively identical spheres is the limiting case as the differences get less and less.

In addition to this rejoinder, it should be noted that in only slightly more complicated examples the identification strategy is rather less persuasive than in the two sphere case. Consider the example of three qualitatively identical spheres arranged in a line, with the two outside ones the same distance from the middle one. The identification strategy would first require the two outer ones to be identified. But in that case there remain two qualitatively identical spheres, so these must in turn be identified. The upshot is that it is not merely the two spheres we took to be indistinguishable that are said to be identical but all three, including the middle one which seemed clearly distinguished from the other two by means of a pure relational property.

Without an appeal to quantum mechanics we have, then, arguments that many find persuasive to show that both the Weak and the Strong Principle are contingently true but neither are necessarily so.

The Impact of Quantum Mechanics

Quantum mechanics has been taken to have implications for the Principle.

(i) Orthodox quantum mechanics tells us that the state of a system of n particles of the same kind is one in which there is nothing to distinguish the particles one from another. That is not to say that they occupy the same position, have the same momentum, and have the same spin, but rather that there is nothing in the many-particle state which says which particle is which. Although controversial as an interpretation, a useful heuristic is to think of all the particles as equally at all the positions they might be in but not determinately at any of them. And likewise for momentum and spin. In that case the particles would seem to be indiscernible, thus showing that even the Weak Principle is false, and that it is false of nomic necessity. (See French 1988, 1989.) Against this it might be argued that a hidden variable interpretation would show that there are in fact several distinct particles each with their own locations, momenta and spins, although we cannot in fact re-identify a particle from one time to another.

(ii) The issue is complicated by Teller's thesis (Teller 1995, Chapter 2) that particles are not individuals at all. The argument for this may be expressed in a way which is neutral on the topic of hidden variables. Consider someone who knows all about quantum mechanics for a single particle and is predicting what is likely for two particles of the same kind. If that person assumes the particles are genuine individuals, whether discernible or otherwise, then it is fairly likely that among all the allowed probability distributions for such quantities as position, momentum and spin there will be some in which the distributions for the two particles are probabilistically independent. But in fact such independence is (nomically) impossible and the resulting distribution, in both the boson and the fermion case, is one of those we might have predicted for particles which are not individuals. This supports Teller's thesis that particles are not individuals, and so, in one respect at least, like waves.

(iii) Teller's thesis relates nicely to a defence of the Principle which I have not yet mentioned, namely that in the prima facie counter-examples the indiscernible entities are not in fact substances. Thus if the only substances were universes, it would be hard to object to even the necessary Strong Principle. Relying on this style of defence we might well deny that the particles are substances. Perhaps the substance is the composite of all the particles of a given kind. Or we could take the regions of spacetime to be the substances and the quantum state as specifying the intrinsic properties of those regions. States with a spatial symmetry are possible but of infinitesimal probability. So we would draw the conclusion that the Strong Principle is contingently true.

The History of the Principle

Leibniz prudently restricts the Principle to substances. Moreover, Leibniz is committed to saying that the extrinsic properties of substances supervene on the intrinsic ones, which collapses the distinction between the strong and the Weak Principles.

Although the details of Leibniz's metaphysics are debatable, the Principle would seem to follow from Leibniz's thesis of the priority of possibility. (See Leibniz's remarks on possible Adams in his 1686 letter to Arnauld, in Loemker 1969, p. 333.) It does not appear to require the Principle of Sufficient Reason,

which Leibniz sometimes bases it on.(See for example Section 21 of Leibniz's fifth paper in his correspondence with Clarke (Loemker 1969, p. 699). See also Rodriguez-Pereyra 1999.) For Leibniz takes God to have created by actualising substances which already exist as possibilia. Hence there could only be indiscernible actual substances if there were indiscernible ones which were merely possible. Hence if the Principle holds for merely possible substances it holds for actual ones as well. There is, therefore, no point in speculating as to whether there might not be a sufficient reason to actualise two of a possible substance, for God cannot do that since both would have to be identical to the one possible substance. The Principle restricted to merely possible substances follows from Leibniz's identification of substances with complete concepts. For two complete concepts must differ in some conceptual respect and so be discernible.

Holism and Nonseparability in Physics

It has sometimes been suggested that quantum phenomena exhibit a characteristic holism or nonseparability, and that this distinguishes quantum from classical physics. One puzzling quantum phenomenon arises when one performs measurements of spin or polarization on certain separated quantum systems. The results of these measurements exhibit patterns of statistical correlation that resist traditional causal explanation. Some have held that it is possible to understand these patterns as instances or consequences of quantum holism or nonseparability. Just what holism and nonseparability are supposed to be has not always been made clear, though, and each of these notions has been understood in different ways. Moreover, while some have taken holism and nonseparability to come to the same thing, others have thought it important to distinguish the two. Any evaluation of the significance of quantum holism and/or nonseparability must rest on a careful analysis of these notions.

Introduction

Holism has often been taken as the thesis that the whole is more than the sum of its parts. Several different interpretations of this epigram prove relevant to physics, as we shall see. Here is a correspondingly vague initial statement of nonseparability: The state of the whole is not constituted by

states of its parts. It is already apparent both that holism and nonseparability are related notions and that their exact relation needs to be clarified.

In one interpretation, holism is a methodological thesis, to the effect that the best way to study the behavior of a complex system is to treat it as a whole, and not merely to analyze the structure and behavior of its component parts. Alternatively, holism may be taken as a metaphysical thesis: There are some wholes whose natures are simply not determined by the nature of their parts. Methodological holism stands opposed to methodological reductionism, in physics as well as in other sciences. But it is a certain variety of metaphysical holism that is more closely related to nonseparability. What is at issue here is the extent to which the properties of the whole are determined by the properties of its parts: property holism denies such determination, and thereby comes very close to a thesis of nonseparability.

By and large, a system in classical physics can be analyzed into parts, whose states and properties determine those of the whole they compose. But the state of a system in quantum mechanics resists such analysis. The quantum state of a system gives a specification of it's probabilistic dispositions to display various properties on measurement. Quantum theory's most complete such specification is given by what is called a pure state. Even when a compound system has a pure state, some of its subsystems may not have their own pure states. Emphasizing this characteristic of quantum mechanics, Schrödinger described such component subsystems as "entangled". Superficially, such entanglement of systems already demonstrates nonseparability. At a deeper level, it has been maintained that the puzzling statistics that arise from measurements on entangled quantum systems either demonstrate, or are explicable in terms of, holism or nonseparability rather than any problematic action at a distance.

The Aharonov-Bohm effect also appears to exhibit action at a distance, as the behavior of electrons is modified by a magnetic field they never experience. But this effect may be understood instead as a result of the local action of nonseparable electromagnetism.

Puzzling correlations arise between distant simultaneous measurements even in the vacuum, according to quantum field theory. Perhaps these, too, are not a result of direct causal connections, but rather a manifestation of some kind of holism or nonseparability?

String theory is an ambitious research program in the framework of quantum field theory. According to string theory, all fundamental particles can be considered to be excitations of underlying non-pointlike entities in a multi-dimensional space. The particles' intrinsic charge, mass and spin may then arise as nonseparable features of the world at the deepest level.

Methodological Holism

Methodologically, holism stands opposed to reductionism, somewhat as follows.

> **Methodological Holism**: An understanding of a certain kind of complex system is best

sought at the level of principles governing the behavior of the whole system, and not at the level of the structure and behavior of its component parts.

Methodological Reductionism: An understanding of a complex system is best sought at the level of the structure and behavior of its component parts.

This seems to capture much of what is at stake in debates about holism in social and biological science. In social science, societies are the complex systems, composed of individuals; while in biology, the complex systems are organisms, composed of cells, and ultimately of proteins, DNA and other molecules. A methodological individualist maintains that the right way to approach the study of a society is to investigate the behavior of the individual people that compose it. A methodological holist, on the other hand, believes that such an investigation will fail to shed much light on the nature and development of society as a whole. There is a corresponding debate within physics. Methodological reductionists favor an approach to (say) condensed matter physics which seeks to understand the behavior of a solid or liquid by applying quantum mechanics (say) to its component molecules, atoms, ions or electrons. Methodological holists think this approach is misguided: As one condensed matter physicist put it "the most important advances in this area come about by the emergence of qualitatively new concepts at the intermediate or macroscopic levels--concepts which, one hopes, will be compatible with one's information about the microscopic constituents, but which are in no sense logically dependent on it." [Leggett (1987), p.113.]

It is surprisingly difficult to find methodological reductionists among physicists. The elementary particle physicist Steven Weinberg, for example, is an avowed reductionist. He believes that by asking any sequence of deeper and deeper why-questions one will arrive ultimately at the same fundamental laws of physics. But this explanatory reductionism is metaphysical in so far as he takes explanation to be an ontic rather than a pragmatic category. On this view, it is not physicists but the fundamental laws themselves that explain why "higher level" scientific principles are the way they are. Weinberg (1992) explicitly distinguishes his view from methodological reductionism by saying that there is no reason to suppose that the convergence of scientific explanations must lead to a convergence of scientific methods.

Metaphysical Holism

The metaphysical holist believes that the nature of some wholes is not determined by that of their parts. One may distinguish three varieties of metaphysical holism: ontological, nomological and property holism.

Ontological Holism: Some objects are not wholly composed of basic physical parts.

Property Holism: Some objects have properties that are not determined by physical properties of their basic physical parts.

> **Nomological Holism**: Some objects obey laws that are not determined by fundamental physical laws governing the structure and behavior of their basic physical parts.

All three theses require an adequate clarification of the notion of a basic physical part. One way to do this would be to consider objects as basic, relative to a given class of objects subjected only to a certain kind of process, just in case every object in that class continues to be wholly composed of a fixed set of these (basic) objects. Thus, atoms would count as basic parts of hydrogen if it is burnt to form water, but not if it is converted into helium by a thermonuclear reaction.

Weinberg's (1992) reductionism is opposed to nomological holism in science. He claims, in particular, that thermodynamics has been explained in terms of particles and forces, which could hardly be the case if thermodynamic laws were autonomous. In fact thermodynamics presents a fascinating but complex test case for the theses both of property holism and of nomological holism. One source of complexity is the variety of distinct concepts of both temperature and entropy that figure in both classical thermodynamics and statistical mechanics. Another is the large number of quite differently constituted systems to which thermodynamics can be applied, including not just gases and electromagnetic radiation but also magnets, chemical reactions, star clusters and black holes. Both sources of complexity require a careful examination of the extent to which thermodynamic properties are determined by the physical properties of the basic parts of thermodynamic systems. A third difficulty stems from the problematic status of the probability assumptions that are required in addition to the basic mechanical laws in order to recover thermodynamic principles within statistical mechanics. (An important example is the assumption that the micro-canonical ensemble is to be assigned the standard, invariant, probability distribution.) Since the basic laws of mechanics do not determine the principles of thermodynamics without some such assumptions (however weak), there may well be at least one interesting sense in which thermodynamics establishes nomological holism.

Property/Relational Holism

While some form of ontological holism has occasionally been considered, the variety of metaphysical holism most clearly at issue in quantum mechanics is property holism. But to see just what the issue is we need a more careful formulation of that thesis.

First the thesis should be contextualized to *physical* properties of composite *physical* objects. We are interested here in how far a physical object's properties are fixed by those of its parts, not in some more general determinationist physicalism. Next, to arrive at an interesting formulation of property holism we must accept that this thesis is not only concerned with properties, and not concerned with all properties. The properties of a whole will typically depend upon *relations* among its proper parts as well as on properties of the individual parts. But if we are permitted to consider *all* properties and relations among the parts, then these trivially determine the properties of the whole they compose. For one relation among the parts is what we might call the complete composition relation--that relation among the parts which holds just in case they compose this very whole with all its properties.

Let us call a canonical set of properties and relations of the parts which may or may not determine the properties and relations of the whole the supervenience basis. To avoid trivializing the theses we are trying to formulate, only certain properties and relations can be allowed in the supervenience basis. The intuition as to which these are is simple--the supervenience basis is to include just the qualitative intrinsic properties and relations of the parts, i.e. the properties and relations which these bear in and of themselves, without regard to any other objects, and irrespective of any further consequences of their bearing these properties for the properties of any wholes they might compose. Unfortunately, this simple intuition resists precise formulation. It is notoriously difficult to say precisely what is meant either by an intrinsic property or relation, or by a purely qualitative property or relation. And the other notions appealed to in expressing the simple intuition are hardly less problematic. But, imprecise as it is, this statement serves already to exclude certain unwanted properties and relations, including the complete composition relation, from the supervenience basis.

Finally, we arrive at the following opposing theses:

> **Physical Property Determination**: Every qualitative intrinsic physical property and relation of a set of physical objects from any domain **D** subject only to type **P** processes supervenes on qualitative intrinsic physical properties and relations in the supervenience basis of their basic physical parts (relative to **D** and **P**).

> **Physical Property Holism**: There is some set of physical objects from a domain **D** subject only to type **P** processes, not all of whose qualitative intrinsic physical properties and relations supervene on qualitative intrinsic physical properties and relations in the supervenience basis of their basic physical parts (relative to **D** and **P**).

There is some residual unclarity in the notion of supervenience that figures in these theses. The idea is familiar enough--that there can be no relevant difference in objects in **D** without a relevant difference in their basic physical parts. I take it that the modality involved here is not logical but broadly physical. One might try to explicate the notion of supervenience here in terms of models of a true, descriptively complete, physical theory. At issue is whether such a physical theory has two models which agree on the qualitative intrinsic physical properties and relations of the basic parts of one or more objects in **D** but disagree on some qualitative intrinsic property or relation of these objects.

Teller (1989) has introduced the related idea of what he calls relational holism.

> **Relational Holism**: There are non-supervening relations--that is, relations that do not supervene on the nonrelational properties of the relata. (p. 214)

Within physics, this specializes to a close relative of physical property holism, namely:

> **Physical Relational Holism**: There are qualitative intrinsic physical relations between some physical objects that do not supervene on their qualitative intrinsic physical

> properties.

Physical property holism entails physical relational holism, but not vice versa. Indeed, physical relational holism seems at first sight too weak to capture any distinctive feature of quantum phenomena: even in classical physics the spatiotemporal relations between physical objects seem not to supervene on their qualitative intrinsic physical properties. But when he introduced relational holism Teller(1987) maintained a view of spacetime as a quantity: On this view spatiotemporal relations do in fact supervene on qualitative intrinsic physical properties of ordinary physical objects, since these include their spatiotemporal properties.

State Nonseparability

Physics treats systems by assigning them states. The thermodynamic state of a gas specifies its pressure, volume and temperature. The state of a system of classical particles is represented in a phase space coordinatized by their positions and momenta, either as a point in that space, or in statistical mechanics by a probability distribution over the space. One expects that if a physical system is composed of physical subsystems, then both the composite system and its subsystems will be assigned states by the relevant physical theory. One further expects that the state of the whole will not be independent of those of its parts, and specifically that if a system is composed of two subsystems, A and B, then it will satisfy a principle formulated by Einstein (1935). Howard (1985, p.180) gives the following translation of this principle, which I will call the

> **Real State Separability Principle**: The real state of the pair AB consists precisely of the real state of A and the real state of B, which states have nothing to do with one another.

But the assignment of states to systems in quantum mechanics seems not to conform to these expectations. Recall that the quantum state of a system gives a specification of its probabilistic dispositions to display various properties on measurement. The mathematical representative of this state is an object defined in a Hilbert space--a kind of vector space. This is somewhat analogous to the representation of the state of a system of particles in classical mechanics in a phase space. Let us formulate a principle of

> **State Separability**: The state assigned to a compound physical system at any time is supervenient on the states then assigned to its component subsystems.

This principle could fail in one of two ways: the subsystems may simply not be assigned any states of their own, or else the states they are assigned may fail to determine the state of the system they compose. Interestingly, state assignments in quantum mechanics have been taken to violate state separability in both ways.

The quantum state of a system may be either pure or mixed. A pure state is represented by a vector in the

system's Hilbert space. On one common understanding, any entangled quantum systems violate state separability in so far as the vector representing the state of the system they compose does not factorize into a vector in the Hilbert space of each individual subsystem that could be taken to represent its pure state. Now in such a case each subsystem *1, 2, ... , n* may be uniquely assigned a what is called a mixed state (represented in its Hilbert space not by a vector but by a so-called von Neumann density operator). But then state separability fails for a different reason: the subsystem mixed states do not uniquely determine the compound system's state. A failure of state separability may not occasion much surprise if states are thought of merely in their role of specifying probabilistic dispositions. But it becomes more puzzling if a system's quantum state also has a role in specifying certain of its categorical properties. For that role may connect a failure of state nonseparability to metaphysical holism and nonseparability.

Spatial and Spatiotemporal Nonseparability

The idea is familiar (particularly to Lego enthusiasts!) that if one constructs a physical object by assembling its physical parts, then the physical properties of that object are wholly determined by the properties of the parts and the way it is put together from them. A principle of spatial separability tries to capture that idea.

> **Spatial Separability**: The qualitative intrinsic physical properties of a compound system are supervenient on those of its spatially separated component systems together with the spatial relations among these component systems.

If we identify the real state of a system with its qualitative intrinsic physical properties, then spatial separability is related to a separability principle stated by Howard (1985, p. 173) to the effect that any two spatially separated systems possess their own separate real states. It is even more closely related to Einstein's (1935) real state separability principle. Indeed, Einstein formulated this principle in the context of a pair A,B of spatially separated systems.

Spatial nonseparability -- the denial of spatial separability -- is closely related to physical property holism (the denial of physical property determination). For spatial relations are the only clear examples of qualitative intrinsic physical relations required in the supervenience basis of the relata in physical property determination: other intrinsic physical relations seem to supervene on them.

If we take a spacetime perspective, then spatial separability naturally generalizes to

> **Spatiotemporal Separability**: Any physical process occupying spacetime region *R* supervenes upon an assignment of qualitative intrinsic physical properties at spacetime points in *R*.

Spatiotemporal separability is a natural restriction to physics of David Lewis's (1986, p. x) principle of Humean supervenience. It is also closely related to another principle formulated by Einstein (1948) in the

following words: "An essential aspect of [the] arrangement of things in physics is that they lay claim, at a certain time, to an existence independent of one another, provided these objects ‘are situated in different parts of space’" (the context of the quote suggests that the "space" Einstein had in mind here was actually spacetime).

As Healey (1991, p. 411) shows, spatiotemporal separability entails spatial separability, and so spatial nonseparability entails spatiotemporal nonseparability. Because it is both more general and more consonant with a geometric spacetime viewpoint, it seems reasonable to consider spatiotemporal separability to be the primary notion, so that nonseparability is understood as its denial.

> **Nonseparability**: Some physical process occupying a region *R* of spacetime is not supervenient upon an assignment of qualitative intrinsic physical properties at spacetime points in *R*.

It is important to note that nonseparability entails neither physical property holism nor spatial nonseparability: a process may be nonseparable even though it involves objects without proper parts.

Holism and Nonseparability in Classical Physics

Classical physics presents no clear examples of either physical property holism or nonseparability. Since any example of physical property holism would give rise to nonseparability, it suffices to consider only the latter possibility. But the assumption that all physical processes are separable forms part of the metaphysical background to classical physics. In Newtonian spacetime, the kinematical behavior of a system of point particles under the action of finite forces would constitute a separable physical process, since it is supervenient upon ascriptions of particular values of position and momentum to the particles along their trajectories during the collision. This separability extends also to their dynamics if the forces arise from fields defined at each spacetime point.

The boiling of a kettle of water is an example of a more complex separable physical process. It consists in the increased kinetic energy of its constituent molecules permitting each to overcome the short range attractive forces which otherwise hold it in the liquid. It thus supervenes on the assignment, at each spacetime point on the trajectory of each molecule, of intrinsic physical properties to that molecule (such as its kinetic energy), together with intrinsic physical properties representing the magnitude and direction of the fields that give rise to the attractive force acting on that molecule at that point.

As an example of a separable process in Minkowski spacetime [the spacetime framework for Einstein's special theory of relativity], consider the propagation of an electromagnetic wave through empty space. This is supervenient upon an ascription of electric and magnetic field vectors at each point in the spacetime.

Any physical process described fully by a local spacetime theory will be separable. For such a theory

proceeds by assigning geometric objects (such as vectors or tensors) to each point in spacetime to represent physical fields, and then requiring that these satisfy certain field equations. But processes described fully by theories of other forms will also be separable. This is true not only of pure field theories, but also of many theories which assign properties to particles at each point on their trajectories. Of familiar classical theories, it is only theories involving direct action between spatially separated particles which involve nonseparability in their description of the dynamical histories of individual particles. But such processes are spatiotemporally separable within spacetime regions that are large enough to include all sources of forces acting on these particles, so that the appearance of nonseparability may be attributed to a mistakenly narrow understanding of the spacetime region these processes actually occupy.

The propagation of gravitational energy according to general relativity apparently involves nonseparable processes, since gravitational energy cannot be localized (it does not contribute to the stress-energy tensor defined at each point of spacetime as do other forms of energy). But even a non-locally-defined gravitational energy will still be supervenient upon the metric tensor defined at each point of the spacetime, and so therefore will be the process of its propagation.

The Quantum Physics of Entangled Systems

A set of entangled quantum systems compose a system whose quantum state is represented quantum mechanically by a tensor-product state-vector which does not factorize into a vector in the Hilbert space of each individual system.

$$\Psi_{1,2,\ldots,n} \neq \Psi_1 \otimes \Psi_2 \otimes \ldots \otimes \Psi_n$$

The quantum states of entangled quantum systems violate state separability. This is not surprising if a system's state merely specifies its probabilistic dispositions for the display of various possible properties on measurement. But it has metaphysical significance if a system's quantum state plays a role in specifying it's categorical properties--it's real state, so that the real state separability principle is threatened. His commitment to this principle is one reason why Einstein denied that a quantum system's real state is given by its quantum state (though it's not clear what he thought its real state consisted in).

Modal interpretations of quantum mechanics endorse Einstein's denial. But what a modal interpretation takes to be the real state of an entangled system may still be closely enough related to quantum states that entangled systems' violation of quantum state separability implies some kind of holism or nonseparability. Van Fraassen (1991, p. 294), for example, sees his modal interpretation as committed to "a strange holism" because it entails that a compound system may fail to have a property corresponding to a tensor product projection operator P×I even though its first component has a property corresponding to P. In fact, a clearer case of holism would arise in a modal interpretation that implied that the component lacked P while the compound had P×I: *ceteris paribus*, that would provide an instance of physical property holism. Other instances of physical property holism arise in the modal interpretation of

Healey (1989), whose rules for property attributions permit a compound quantum system to possess holistic properties--dynamical properties that do not supervene on those of their component quantum systems.

Some have located a kind of holism or nonseparability in the probabilities for results of measurements performed on spatially separated entangled systems. Quantum mechanics predicts the probability distributions for combinations of joint and single measurements of variables including spin and polarization on each of a pair of entangled systems, and many of these distributions have been experimentally verified. The joint probability distributions do not factorize into the product of two independent single distributions. If one thinks that quantum mechanics treats each dynamical variable by replacing a precise real value assignment by a probability distribution for the results of measurements of that dynamical variable, then one might see this already as a violation of the real state separability principle. But if one entertains a theory that supplements the quantum state by values of additional "hidden" variables, then the quantum mechanical probabilities would be taken to arise from averaging over many distinct hidden states. In that case, it would rather be the probability distribution conditional on a complete specification of the values of the hidden variables that should be taken to constitute irreducible dispositions of the system concerned. The real state would then include all these conditional probability distributions.

Such reasoning led Howard (1989,1992) to take outcome independence--the probabilistic independence of the outcomes of a given pair of measurements, one on each of a pair of entangled systems, conditional on definite values for any assumed hidden variables on the joint system--as a separability condition. Outcome independence is closely related to parameter independence--the condition that, given a definite hidden variable assignment, the outcome of a measurement on one of a pair of entangled systems is probabilistically independent of what measurement, if any, is made on the other system. Together with parameter independence, outcome independence implies so-called Bell inequalities. These inequalities constrain the patterns of statistical correlations to be expected between the results of measurements of variables including spin and polarization on a pair of entangled systems in any quantum state. They are often said to constrain the predictions of any local hidden variable theory: this is true to the extent that parameter and outcome independence succeed in expressing locality conditions. Quantum mechanics predicts, and experiment confirms, that such Bell inequalities do not always hold. Howard (1989), as well as Teller (1989), suggested that we understand this as stemming from a failure not of parameter independence but of outcome independence, and that this failure is consequently associated with holism or nonseparability. Howard (1989) blames the violation of Bell inequalities on the violation of his separability condition: Teller (1989) takes it to be a manifestation of relational holism. They both acquit parameter independence of blame because they believe that (at least when the measurement events on the entangled systems are spacelike separated) parameter independence (unlike outcome independence) is a consequence of relativity theory.

Others have questioned this line of reasoning, including the conclusion that its appeal to holism or nonseparability helps one to understand how these correlations involving entangled systems come about without any action at a distance that violates either relativity theory or the

> **Principle of Local Action**: If A and B are spatially distant things, then an external influence on A has no immediate effect on B.

Howard's (1989,1992) identification of outcome independence with a separability condition has proved controversial, as has Teller's (1989) claim that violations of Bell inequalities are no longer puzzling if one embraces (physical) relational holism [Laudisa (1995), Berkowitz (1998)]. And the view that violations of outcome independence are perfectly consistent with relativity theory, while violations of parameter independence are not, has also been criticized [Jones and Clifton (1993), Maudlin (1994)].

Healey (1989,1994) has offered a modal interpretation and used it to present a model account of the puzzling correlations which portrays them as resulting from the operation of a process that violates both spatial and spatiotemporal separability. He argues that, on this interpretation, the nonseparability of the process is a consequence of a violation of physical property holism; and that the resulting account yields genuine understanding of how the correlations come about without any violation of relativity theory or the principle of local action. But subsequent work by Clifton and Dickson (1998) has cast doubt on whether the account can be squared with relativity theory's requirement of Lorentz invariance.

Ontological Holism in Quantum Mechanics?

As applied to physics, ontological holism is the thesis that there are physical objects that are not wholly composed of basic physical parts. Views of Bohr, Bohm and others may be interpreted as endorsing some version of this thesis. In no case is it claimed that any physical object has *non*physical parts. The idea is rather that some physical entities that we take to be wholly composed of a particular set of basic physical parts are in fact not so composed.

It was Bohr's (1934) view that one can meaningfully ascribe properties such as position or momentum to a quantum system only in the context of some well-defined experimental arrangement suitable for measuring the corresponding property. He used the expression ‘quantum phenomenon’ to describe what happens in such an arrangement. In his view, then, although a quantum phenomenon is purely physical, it is not composed of distinct happenings involving independently characterizable physical objects--the quantum system on the one hand, and the classical apparatus on the other. And even if the quantum system may be taken to exist outside the context of a quantum phenomenon, little or nothing can then be meaningfully said about its properties. It would therefore be a mistake to consider a quantum object to be an independently existing component part of the apparatus-object whole.

Bohm's (1980,1993) reflections on quantum mechanics lead him to adopt a more general holism. He believed that not just quantum object and apparatus, but any collection of quantum objects by themselves, constitute an indivisible whole. This may be made precise in the context of Bohm's (1952) interpretation of quantum mechanics by noting that a complete specification of the state of the "undivided universe" requires not only a listing of all its constituent particles and their positions, but also of a field associated with the wave-function that guides their trajectories. If one assumes that the basic

physical parts of the universe are just the particles it contains, then this establishes ontological holism in the context of Bohm's interpretation.

Some [Howard (1989), Dickson (1998)] have connected the failure of a principle of separability to ontological holism in the context of violations of Bell inequalities. Howard (1989) states the following separability principle (pp. 225-6)

> The contents of any two regions of space-time separated by a nonvanishing spatiotemporal interval constitute separable physical systems, in the sense that (1) each possesses its own, distinct physical state, and (2) the joint state of the two systems is wholly determined by these separate states.

He takes Einstein to defend this as a principle of individuation of physical systems, without which physical thought "in the sense familiar to us" would not be possible. Howard himself contemplates the possible failure of this principle for entangled quantum systems, with the consequence that these could no longer be taken to be wholly composed of what are typically regarded as their subsystems. Dickson (1998), on the other hand, argues that such holism is not "a tenable scientific doctrine, much less an explanatory one" (p. 156).

One may try to avoid the conclusion that experimental violations of Bell inequalities manifest a failure of Local Action by invoking ontological holism for events. The idea would be to deny that these experiments involve distinct, spatiotemporally separate, measurement events, and to maintain instead that what we usually describe as separate measurements involving an entangled system in fact constitute one indivisible, spatiotemporally disconnected, event with no spatiotemporal parts. But such ontological holism conflicts with the criteria of individuation of events inherent in both quantum theory and experimental practice.

The Aharonov-Bohm Effect

Aharonov and Bohm (1959) drew attention to the quantum mechanical prediction that an interference pattern due to a beam of charged particles could be produced or altered by the presence of a constant magnetic field in a region from which the particles were excluded. This effect has since been experimentally demonstrated. At first sight, the Aharonov-Bohm effect seems to involve action at a distance. It seems clear that the (electro-)magnetic field acts on the particles since it affects the interference pattern they produce; and this must be action at a distance since the particles pass through a region from which that field is absent. But alternative accounts of the phenomenon are possible which portray it rather as a manifestation of nonseparability [Healey (1997)]. There need be no action at a distance if the behavior both of the charged particles and of electromagnetism are nonseparable processes. While such a treatment of electromagnetism (and other gauge theories) is increasingly common in physics, to treat the motion of the charged particles as a nonseparable process is to endorse a particular position on how quantum mechanics is to be interpreted.

An interpretation of quantum mechanics that ascribes a nonlocalized position to a charged particle on its way through the apparatus is committed to a violation of spatiotemporal separability in the Aharonov-Bohm effect, since the particle's passage constitutes a nonseparable process. To see why the electromagnetism that acts on the particles during their passage may also be taken to be nonseparable it is necessary to consider contemporary representations of electromagnetism in terms of neither fields nor potentials.

Following Wu and Yang's (1975) analysis of the Aharonov-Bohm effect, it has become common to consider electromagnetism to be completely and nonredundantly described neither by the electromagnetic field, nor by its generating potential, but rather by the so-called Dirac phase factor:

$$\exp\left[-(ie/\hbar)\oint_C A_\mu(x^\mu).dx^\mu\right]$$

where A_μ is the electromagnetic potential at spacetime point x^μ, e is the particles' charge, and the integral is taken over each closed loop C in spacetime. Applied to the Aharonov-Bohm case, this means that the constant magnetic field is accompanied by an association of a phase factor $S(C)$ with all closed curves C in space, where $S(C)$ is defined by

$$S(C) = \exp\left[-(ie/\hbar)\oint_C \mathbf{A}(\mathbf{r}).d\mathbf{r}\right]$$

This approach has the advantage that since $S(C)$ is gauge-invariant, it may readily be considered a physically real quantity. Moreover, the effects of electromagnetism in the field-free region may be attributed to the fact that $S(C)$ is nonvanishing for certain closed curves C within that region. But it is significant that, unlike the magnetic field and its potential, $S(C)$ is not defined at each point of space at each moment of time.

Can $S(C)$ at some time be taken to represent an intrinsic property of a region of space corresponding to the curve C? There are two difficulties with this suggestion. The first is that the presence of the quantity e in the definition of $S(C)$ appears to indicate that $S(C)$ rather codes the effect of electromagnetism on objects with that specific charge. If in fact *all* charges are multiples of some minimal value e, then this would no longer be a problem: the fact that $S(C)$ at some time represents an intrinsic property of a region of space corresponding to the curve C would be a natural reflection of this fact. If not, one could rather take

$$I(C) = \oint_C \mathbf{A}(\mathbf{r}).d\mathbf{r}$$

to be an intrinsic property of C. The second difficulty is that closed curves do not correspond uniquely to regions of space: e.g. circling the region in which there is a magnetic field twice on the same circle will

produce a different curve from circling it once. But this does not prevent one from taking $S(C)$ at some time to represent an intrinsic property of the region of space occupied by a nonself-intersecting closed curve C.

Once these difficulties have been handled, it is indeed possible to consider electromagnetism in the Aharonov-Bohm effect as faithfully represented at a time by a set of intrinsic properties of regions of space occupied by nonself-intersecting closed curves. But if one does so, then electromagnetism itself manifests nonseparability. For these intrinsic properties do not supervene on any assignment of qualitative intrinsic physical properties at spacetime points in the region concerned. Whether the magnetic field remains constant or changes, the associated electromagnetism constitutes a nonseparable process, and so the Aharonov-Bohm effect violates spatiotemporal separability. If the motion of the particles through the apparatus is a nonseparable process, then it is possible to account for the AB effect in terms of a purely local interaction between (nonseparable) electromagnetism and this process. For the particles effectively traverse closed curves C on their nonlocalized "trajectories", and so they interact with electromagnetism precisely where this is defined.

Even if the Aharonov-Bohm effect does exhibit such nonseparability, there is no violation of physical property holism (or, indeed, spatial separability). This makes it clear by example that holism and nonseparability are indeed distinct, though related, notions.

Quantum Field Theory

Certain phenomena that arise within quantum field theory have been taken as instances of nonseparability. As in the Aharonov-Bohm effect, this seems not to result from either physical property holism or a violation of spatial separability.

It is well known that even in the vacuum state, quantum field theory predicts statistical correlations between the results of measurements even if these occur in regions that cannot be connected by a light signal. At least in certain special cases, these correlations imply violations of Bell inequalities. No compound systems like photon pairs are involved, so it is hard to see how this can be explained by appeal to physical property holism or spatial nonseparability (though one might argue that in this context spacetime regions constitute the relevant quantum systems, with the subsystem relation corresponding to containment). But it is not unreasonable to suggest that the correlations reflect some failure of spatiotemporal separability. Whether this is true or not depends on whether it is possible to understand the results of simultaneous measurements in quantum field theory as reflecting some intrinsic physical property associated with the disconnected spacetime region occupied by the measurement events.

Wayne (1998) has suggested that quantum field theory is best interpreted as postulating extensive holism or nonseparability. On this interpretation, the fundamental quantities in quantum field theory are vacuum expectation values of products of field operators defined at various spacetime points. The field can be reconstructed out of all of these. Nonseparability supposedly arises because the vacuum expectation

value of a product of field operators defined at an *n*-tuple of distinct spacetime points does not supervene on qualitative intrinsic physical properties defined at those *n* points, together with the spatiotemporal relations among the points.

But it is not clear that vacuum expectation values of products of field operators defined at *n*-tuples of distinct spacetime points represent either qualitative intrinsic physical properties of these n-tuples or physical relations between them. Evaluation of the extent to which quantum field theory illustrates holism or nonseparability must await further progress in the interpretation of quantum field theory. (Redhead(1995) represents a relevant first step.)

String Theory

At the turn of the 21st century, string theory (or its descendant, *M*-theory) has emerged as a speculative candidate for unifying much of fundamental physics, including quantum mechanics and general relativity. Existing string theories proceed by quantizing classical theories of basic entities that are extended in one or more dimensions of a space that has 6 or 7 tiny compact dimensions in addition to the three spatial dimensions of ordinary geometry. If these additional dimensions are appropriately considered spatial, then it is natural to extend the concepts of spatial and spatiotemporal separability to encompass them. In that case, processes involving classical strings (or *p*-branes with $p > 0$) would count as (spatiotemporally) nonseparable, even though all particles and their properties conform to spatial separability.

The status of nonseparability within a quantized string field theory is not so easy to assess, because of the general problems associated with deciding what the ontology of any relativistic quantum field theory should be taken to be.

Collapse Theories

Quantum mechanics, with its revolutionary implications, has posed innumerable problems to philosophers of science. In particular, it has suggested reconsidering basic concepts such as the existence of a world that is, at least to some extent, independent of the observer, the possibility of getting reliable and objective knowledge about it, and the possibility of taking (under appropriate circumstances) certain properties to be objectively possessed by physical systems. It has also raised many others questions which are well known to those involved in the debate on the interpretation of this pillar of modern science. One can argue that most of the problems are not only due to the intrinsic revolutionary nature of the phenomena which have led to the development of the theory. They are also related to the fact that, in its standard formulation and interpretation, quantum mechanics is a theory which is excellent (in fact it has met with a success unprecedented in the history of science) in telling us everything about *what we observe*, but it meets with serious difficulties in telling us *what is*. We are making here specific reference to the central problem of the theory, usually referred to as *the measurement problem*, or, with a more appropriate term, as the *macro-objectification problem*. It is just one of the many attempts to overcome the difficulties posed by this problem that has led to the development of *Collapse Theories*, i.e., to the *Dynamical Reduction Program* (DRP). As we shall see, this approach consists in accepting that the dynamical equation of the standard theory should be modified by the addition of stochastic and nonlinear terms. The nice fact is that the resulting theory is capable, on the basis of a unique dynamics which is assumed to govern all natural processes, to account at the same time for all well-established facts about microscopic systems as described by the standard theory as well as for the so-called postulate of wave packet reduction (WPR). As is well known, such a postulate is assumed in the standard scheme just in order to guarantee that *measurements have outcomes* but, as we shall discuss below, it meets with insurmountable difficulties if one takes the measurement itself to be a process governed by the linear laws of the theory. Finally, the collapse theories account in a completely satisfactory way for the classical behavior of macroscopic systems.

Two specifications are necessary in order to make clear from the beginning what are the limitations and the merits of the program. The only satisfactory explicit models of this type (which are essentially variations and refinements of the one, usually referred to as the GRW theory, proposed in refs. [Ghirardi, Rimini and Weber, 1985, 1986]) are phenomenological attempts to solve a foundational problem. At present, they involve phenomenological parameters which, if the theory is taken seriously, acquire the status of new constants of nature. Moreover, up to now, all attempts to build satisfactory relativistic generalizations of these models have met with serious mathematical difficulties due to the appearance of untractable divergences, even though they elucidate some crucial points and suggest that there is no reason of principle preventing to reach this goal.

In spite of the above remarks, we think that Collapse Theories have a remarkable relevance, since they represent a new way to overcome the difficulties of the formalism, to *close the circle* in the precise sense defined by Abner Shimony [Shimony, 1989], a way which until a few years ago was considered impracticable, and which, on the contrary, has been shown to be perfectly viable. Moreover, they have allowed a clear identification of the formal features which should characterize any unified theory of micro and macro processes.

---

1. General Considerations

As stated already, a very natural question which all scientists who are concerned about the meaning and the value of science have to face, is whether one can develop a coherent worldview that can accommodate our knowledge concerning natural phenomena as it is embodied in our best theories. Such a program meets serious difficulties with quantum mechanics, essentially because of two formal aspects of the theory which are common to all of its versions, from the original nonrelativistic formulations of the 1920s, to the quantum field theories of recent years: the linear nature of the state space and of the evolution equation, i.e., the validity of the superposition principle and the related phenomenon of entanglement, which, in Schrödinger's words:

> is not one but the characteristic trait of quantum mechanics, the one that enforces its entire departure from classical lines of thought [Schrödinger, 1935, p. 807].

These two formal features have embarrassing consequences, since they imply

- objective chance in natural processes, i.e., the nonepistemic nature of quantum probabilities;
- objective indefiniteness of physical properties both at the micro and macro level;
- objective entanglement between spatially separated and non-interacting constituents of a composite system, entailing a sort of holism and a precise kind of nonlocality.

For the sake of generality, we shall first of all present a very concise sketch of ‘the rules of the game’.

2. The Formalism: A Concise Sketch

Let us recall the axiomatic structure of quantum theory:

1. States of physical systems are associated with normalized vectors in a Hilbert space, a complex, infinite-dimensional, linear vector space equipped with a scalar product. Linearity implies that the superposition principle holds: if |*f*> is a state and |*g*> is a state, then (for *a* and *b* arbitrary complex numbers) also

   $$|K> = a|f> + b|g>$$

   is a state. Moreover, the state evolution is linear, i.e., it preserves superpositions: if |*f*,*t*> and |*g*,*t*> are the states obtained by evolving the states |*f*,0> and |*g*,0>, respectively, from the initial time *t*=0 to the time *t*, then *a*|*f*,*t*> + *b*|*g*,*t*> is the state obtained by the evolution of *a*|*f*,0> + *b*|*g*,0>. Finally, the completeness assumption is made, i.e., that the knowledge of its statevector represents, in principle, the most accurate information one can have about the state of an individual physical system.

2. The observable quantities are represented by self-adjoint operators B on the Hilbert space. The associated eigenvalue equations $B|b_k> = b_k|b_k>$ and the corresponding eigenmanifolds (the linear manifolds spanned by the eigenvectors associated to a given eigenvalue, also called eigenspaces) play a basic role for the predictive content of the theory. In fact:

   i. The eigenvalues b_k of an operator B represent the only possible outcomes in a measurement of the corresponding observable.

ii. The norm (i.e. the length) of the projection of the normalized vector (i.e. of length 1) describing the state of the system onto the eigenmanifold associated to a given eigenvalue gives the probability of obtaining the corresponding eigenvalue as the outcome of the measurement. In particular, it is useful to recall that when one is interested in the probability of finding a particle at a given place, one has to resort to the so-called configuration space representation of the statevector. In such a case the statevector becomes a square-integrable function of the position variables of the particles of the system, whose modulus squared yields the probability density for the outcomes of position measurements.

We stress that, according to the above scheme, quantum mechanics makes only conditional probabilistic predictions (conditional on the measurement being actually performed) for the outcomes of prospective (and in general incompatible) measurement processes. Only if a state belongs already before the act of measurement to an eigenmanifold of the observable which is going to be measured, can one predict the outcome with certainty. In all other cases -- if the completeness assumption is made -- one has objective nonepistemic probabilities for different outcomes.

The orthodox position gives a very simple answer to the question: what determines the outcome when different outcomes are possible? Nothing -- the theory is complete and, as a consequence, it is illegitimate to raise any question about possessed properties referring to observables for which different outcomes have non-vanishing probabilities of being obtained. Correspondingly, the referent of the theory are the results of measurement procedures. These are to be described in classical terms and involve in general mutually exclusive physical conditions.

As regards the legitimacy of attributing properties to physical systems, one could say that quantum mechanics warns us against requiring too many properties to be actually possessed by physical systems. However -- with Einstein -- one can adopt as a sufficient condition that one be able (without in any way disturbing the system) to predict with certainty the outcome of a measurement. In this case then, whenever the overall statevector factorizes into the product of a state of the Hilbert space of the physical system S and of the rest of the world, S does possess some properties (actually a complete set of properties, i.e., those associated to a maximal set of commuting observables).

Before concluding this section we must add some comments about the measurement process. Quantum theory was created to deal with microscopic phenomena. In order to obtain information about them one must be able to establish strict correlations between the states of the microscopic systems and the states of objects we can perceive. Within the formalism, this is described by considering appropriate micro-macro interactions. The fact that when the measurement is completed one can make statements about the outcome is accounted for by the already mentioned WPR postulate [Dirac, 1948]: *a measurement always causes a system to jump in an eigenstate of the observed quantity*. Correspondingly, also the statevector of the apparatus ‘jumps’ into the manifold associated to the recorded outcome.

3. The Macro-Objectification Problem

In this Section we shall clarify why the formalism we have just presented gives rise to the measurement or macro-objectification problem. To this purpose we shall, first of all, discuss the standard oversimplified argument based on the so-called von Neumann ideal measurement scheme. Then we shall discuss more recent results [Bassi and Ghirardi, 2000], which relinquish von Neumann's assumptions.

Let us begin by recalling the basic points of the standard argument:

> Suppose that a microsystem *S*, just before the measurement of an observable *B*, is in the eigenstate $|b_j>$ of the corresponding operator. The apparatus (a macrosystem) used to gain information about *B* is initially assumed to be in a precise macroscopic state, its ready state, corresponding to a definite macro property -- e.g., its pointer points at 0 on a scale. Since the apparatus *A* is made of elementary particles, atoms and so on, it must be described by quantum mechanics, which will associate to it the state vector $|A_0>$. One then assumes that there is an appropriate system-apparatus interaction lasting for a finite time, such that when the initial apparatus state is triggered by the state $|b_j>$ it ends up in a final configuration $|A_j>$, which is macroscopically distinguishable from the initial one and from the other configurations $|A_k>$ in which it would end up if triggered by a different eigenstate $|b_k>$. Moreover, one assumes that the system is left in its initial state. In brief, one assumes that one can dispose things in such a way that the system-apparatus interaction can be described as:
>
> (1) (*initial state*): $|b_k>|A_0>$
>
> (*final state*): $|b_k>|A_k>$
>
> Equation (1) and the hypothesis that the superposition principle governs all natural processes tell us that, if the initial state of the microsystem is a linear superposition of different eigenstates (for simplicity we will consider only two of them), one has:
>
> (2) (*initial state*): $(a|b_k> + b|b_j>)|A_0>$
>
> (*final state*): $(a|b_k>|A_k> + b|b_j>|A_j>)$.

Some remarks about this are in order:

- The scheme is highly idealized, both because it takes for granted that one can prepare the apparatus in a precise state, which is impossible since we cannot have control over all its degrees of freedom, and because it assumes that the apparatus registers the outcome without altering the state of the measured system. However, as we shall discuss below, these assumptions are by no means essential to derive the embarrassing conclusion we have to face, i.e., that the final state is a

linear superposition of two states corresponding to two macroscopically different states of the apparatus. Since we know that the + representing linear superpositions cannot be replaced by the logical alternative *either* ... *or*, the measurement problem arises: what meaning can one attach to a state of affairs in which two macroscopically and perceptively different states occur simultaneously?

- As already mentioned, the standard solution to this problem is given by the WPR postulate: in a measurement process reduction occurs: the final state is not the one appearing at the right hand side. of Eq.(2) but, since macro-objectification takes place, it is

(3) either $|b_k>|A_k>$ or $|b_j>|A_j>$ with probabilities $|a|^2$ and $|b|^2$, respectively.

Nowadays, there is a general consensus that this solution is absolutely unacceptable for two basic reasons:

1. It corresponds to assuming that the linear nature of the theory is broken at a certain level. Thus, quantum theory is unable to explain how it can happen that the apparata behave as required by the WPR postulate (which is one of the axioms of the theory).

2. Even if one were to accept that quantum mechanics has a limited field of applicability, so that it does not account for all natural processes and, in particular, it breaks down at the macrolevel, it is clear that the theory does not contain any precise criterion for identifying the borderline between micro and macro, linear and nonlinear, deterministic and stochastic, reversible and irreversible. To use J.S. Bell's words, there is nothing in the theory fixing such a borderline and the *split* between the two above types of processes is fundamentally *shifty*. As a matter of fact, if one looks at the historical debate on this problem, one can easily see that it is precisely by continuously resorting to this ambiguity about the split that adherents of the Copenhagen orthodoxy or *easy solvers* [Bell, 1990] of the measurement problem have rejected the criticism of the *heretics* [Gottfried, 2000]. For instance, Bohr succeeded in rejecting Einstein's criticisms at the Solvay Conferences by stressing that some macroscopic parts of the apparatus had to be treated fully quantum mechanically; von Neumann and Wigner displaced the split by locating it between the physical and the conscious (but what is a conscious being?), and so on. Also other proposed solutions to the problem, notably certain versions of many-worlds interpretations, suffer from analogous ambiguities.

It is not our task to review here the various attempts to solve the above difficulties. One can find many exhaustive treatments of this problem in the literature. On the contrary, we would like to discuss how the macro-objectification problem is indeed a consequence of very general, in fact unavoidable, assumptions on the nature of measurements, and not specifically of the assumptions of von Neumann's model. This was established in a series of theorems of increasing generality, notably the ones by Fine [1970], Shimony [1974], Brown [1986] and Busch and Shimony [1996]. Possibly the most general and direct proof is given by Bassi and Ghirardi [2000], whose results we briefly summarize. The assumptions of the theorem are:

(i) that a microsystem can be prepared in two different eigenstates of an observable (such as, e.g., the spin component along the z-axis) and in a superposition of two such states;

(ii) that one has a sufficiently reliable way of ‘measuring’ such an observable, meaning that when the measurement is triggered by each of the two above eigenstates, the process leads in the vast majority of cases to macroscopically and perceptually different situations of the universe. This requirement allows for cases in which the experimenter does not have perfect control of the apparatus, the apparatus is entangled with the rest of the universe, the apparatus makes mistakes, or the measured system is altered or even destroyed in the measurement process;

(iii) that all natural processes obey the linear laws of the theory.

From these very general assumptions one can show that, repeating the measurement on systems prepared in the superposition of the two given eigenstates, in the great majority of cases one ends up in a superposition of macroscopically and perceptually different situations of the whole universe. If one wishes to have an acceptable final situation, one mirroring the fact that we have definite perceptions, one is arguably compelled to break the linearity of the theory at an appropriate stage.

4. The Birth of Collapse Theories

The debate on the macro-objectification problem continued for many years after the early days of quantum mechanics. In the early 1950s an important step was taken by D. Bohm who presented [Bohm, 1952] a mathematically precise deterministic completion of quantum mechanics (see the entry on Bohmian Mechanics). In the area of Collapse Theories, one should mention the contribution by Bohm and Bub [1966], which was based on the interaction of the statevector with Wiener -- Siegel hidden variables. But let us come to Collapse Theories in the sense currently attached to this expression.

Various investigations during the 1970s can be considered as preliminary steps for the subsequent developments. In the years 1970-1973 L. Fonda, A. Rimini, T. Weber and myself were seriously concerned with quantum decay processes and in particular with the possibility of deriving, within a quantum context, the exponential decay law [Fonda, Ghirardi, Rimini and Weber; 1973, Fonda *et al.*, 1978]. Some features of this approach are extremely relevant for the DRP. Let us list them:

- One deals with individual physical systems;
- The statevector is supposed to undergo random processes at random times, inducing sudden changes driving it either within the linear manifold of the unstable state or within the one of the decay products;
- To make the treatment quite general (the apparatus does not know which kind of unstable system it is testing) one is led to identify the random processes with localization processes of the relative coordinates of the decay fragments. Such an assumption, combined with the peculiar resonant

dynamics characterizing an unstable system, yields, completely generally, the desired result. The 'relative position basis' is the preferred basis of this theory;

- We have applied analogous ideas to measurement processes [Fonda, Ghirardi and Rimini, 1973];
- The final equation for the evolution at the ensemble level is of the quantum dynamical semigroup type and has a structure extremely similar to the final one of the GRW theory.

Obviously, in these papers the reduction processes which are involved were not assumed to be 'spontaneous and fundamental' natural processes, but due to system-environment interactions.

Almost in the same years, P. Pearle [Pearle, 1976,1979], and subsequently N. Gisin [Gisin, 1984] and others, had entertained the idea of accounting for the reduction process in terms of a stochastic differential equation. However, they had not given any general suggestion about how to identify the states to which the dynamical equation should lead. Indeed, these states were assumed to depend on the particular measurement process one was considering. Without a clear indication on this point there was no way to identify a mechanism whose effect could be negligible for microsystems but extremely relevant for the macroscopic ones. N. Gisin gave subsequently an extremely interesting proof [Gisin, 1989] that nonlinear modifications of the standard equation without stochasticity are unacceptable since they imply the possibility of sending superluminal signals. Soon afterwards, R. Grassi and myself [Ghirardi and Grassi, 1991] showed that stochastic modifications without nonlinearity can at most induce ensemble and not individual reductions, i.e., they do not guarantee that the state vector of each individual physical system is driven in a manifold corresponding to definite properties.

5. The Original Collapse Model

As already mentioned, the Collapse Theory [Ghirardi, Rimini and Weber, 1986] we are going to describe amounts to accepting a modification of the standard evolution law of the theory such that microprocesses and macroprocesses are governed by a unique dynamics. Such a dynamics must imply that the micro-macro interaction in a measurement process leads to WPR. Bearing this in mind, recall that the characteristic feature distinguishing quantum evolution from WPR is that, while Schrödinger's equation is linear and deterministic (at the wave function level), WPR is nonlinear and stochastic. It is then natural to consider, as was suggested in the above papers, the possibility of nonlinear and stochastic modifications of the standard Schrödinger dynamics. However, the initial attempts to implement this idea were unsatisfactory for various reasons. The first, which we have already discussed, concerns the choice of the preferred basis: if one wants to have a universal mechanism leading to reductions, to which linear manifolds should the reduction mechanism drive the statevector? Or, equivalently, which of the (generally) incompatible 'potentialities' of the standard theory should we choose to make actual? The second, referred to as the trigger problem by Pearle [Pearle, 1989], is the problem of how the reduction mechanism can become more and more effective in going from the micro to the macro domain. The solution to this problem constitutes the central feature of the Collapse Theories of the GRW type. To discuss these points, let us briefly review the first consistent Collapse model [Ghirardi, Rimini and Weber, 1985] to appear in the literature.

Within such a model, originally referred to as QMSL (Quantum Mechanics with Spontaneous Localizations), the problem of the choice of the preferred basis is solved by remarking that the most embarrassing superpositions, at the macroscopic level, are those involving different spatial locations of macroscopic objects. Actually, as Einstein has stressed [Born, 1971, p. 223], this is a crucial point which has to be faced by anybody aiming to take a macro-objective position about natural phenomena: ‘A macro-body must always have a quasi-sharply defined position in the objective description of reality’. Accordingly, QMSL considers the possibility of spontaneous processes, which are assumed to occur instantaneously and at the microscopic level, which tend to suppress the linear superpositions of differently localized states. The required trigger mechanism must then follow consistently.

The key assumption of QMSL is the following: each elementary constituent of any physical system is subjected, at random times, to random and spontaneous localization processes (which we will call hittings) around appropriate positions. To have a precise mathematical model one has to be very specific about the above assumptions; in particular one has to make explicit HOW the process works, i.e. which modifications of the wave function are induced by the localizations, WHERE it occurs, i.e. what determines the occurrence of a localization at a certain position rather than at another one, and finally WHEN, i.e. at what times, it occurs. The answers to these questions are as follows.

Let us consider a system of N distinguishable particles and let us denote by $F(\boldsymbol{q}_1, \boldsymbol{q}_2, \ldots, \boldsymbol{q}_N)$ the coordinate representation (wave function) of the state vector (we disregard spin variables since hittings are assumed not to act on them).

(a) The answer to the question HOW is then: if a hitting occurs for the i-th particle at point $\boldsymbol{x}$, the wave function is instantaneously multiplied by a Gaussian function (appropriately normalized)

$$G(\boldsymbol{q}_i, \boldsymbol{x}) = K \exp[-(1/2\, d^2)(\boldsymbol{q}_i - \boldsymbol{x})^2],$$

where d represents the localization accuracy. Let us denote as

$$L_i(\boldsymbol{q}_1, \boldsymbol{q}_2, \ldots, \boldsymbol{q}_N ; \boldsymbol{x}) = F(\boldsymbol{q}_1, \boldsymbol{q}_2, \ldots, \boldsymbol{q}_N)\, G(\boldsymbol{q}_i, \boldsymbol{x})$$

the wave function immediately after the localization, as yet unnormalized.

(b) As concerns the specification of WHERE the localization occurs, it is assumed that the probability density $P(\boldsymbol{x})$ of its taking place at the point $\boldsymbol{x}$ is given by the norm of the state L_i (the length, or to be more precise, the integral of the modulus squared of the function L_i over the $3N$-dimensional space). This implies that hittings occur with higher probability at those places where, in the standard quantum description, there is a higher probability of finding the particle. Note that the above prescription introduces nonlinear and stochastic elements in the dynamics. The constant K appearing in the expression of $G(\boldsymbol{q}_i,\boldsymbol{x})$ is chosen

in such a way that the integral of $P(\boldsymbol{x})$ over the whole space equals 1.

(c) Finally, the question WHEN is answered by assuming that the hittings occur at randomly distributed times, according to a Poisson distribution, with mean frequency *f*.

It is straightforward to convince oneself that the hitting process leads, when it occurs, to the suppression of the linear superpositions of states in which the same particle is well localized at different positions separated by a distance greater than *d*. As a simple example we can consider a single particle whose wavefunction is different from zero only in two small and far apart regions *h* and *t*. Suppose that a localization occurs around *h*; the state after the hitting is then appreciably different from zero only in a region around *h* itself. A completely analogous argument holds for the case in which the hitting takes place around *t*. As concerns points which are far from both *h* and *t*, one easily sees that the probability density for such hittings , according to the multiplication rule determining L_i, turns out to be practically zero, and moreover, that if such a hitting were to occur, after the wave function is normalized, the wave function of the system would remain almost unchanged.

We can now discuss the most important feature of the theory, i.e., the Trigger Mechanism. To understand the way in which the spontaneous localization mechanism is enhanced by increasing the number of particles which are in far apart spatial regions (as compared to *d*), one can consider, for simplicity, the superposition |*S*>, with equal weights, of two macroscopic pointer states |*H*> and |*T*>, corresponding to two different pointer positions *H* and *T*, respectively. Taking into account that the pointer is ‘almost rigid’ and contains a macroscopic number *N* of microscopic constituents, the state can be written, in obvious notation, as:

(4) $|S\rangle = [|1 \text{ near } h_1\rangle \ldots |N \text{ near } h_N\rangle + |1 \text{ near } t_1\rangle \ldots |N \text{ near } t_N\rangle]$,

where h_i is near *H*, and t_i is near *T*. The states appearing in first term on the right-hand side of Eq. (4) have coordinate representations which are different from zero only when their arguments (1,...,*N*) are all near *H*, while those of the second term are different from zero only when they are all near *T*. It is now evident that if any of the particles (say, the *i*-th particle) undergoes a hitting process, e.g. near the point h_i, the multiplication prescription leads practically to the suppression of the second term in (4). Thus any spontaneous localization of any of the constituents amounts to a localization of the pointer. The hitting frequency is therefore effectively amplified proportionally to the number of constituents. Notice that, for simplicity, the argument makes reference to an almost rigid body, i.e. to one for which all particles are around *H* in one of the states of the superposition and around *T* in the other. It should however be obvious that what really matters in amplifying the reductions is the number of particles which are in different positions in the two states appearing in the superposition itself.

Under these premises we can now proceed to choose the parameters *d* and *f* of the theory, i.e., the localization accuracy and the mean localization frequency. The argument just given allows one to understand how one can choose the parameters in such a way that the quantum predictions for microscopic systems remain fully valid while the embarrassing macroscopic superpositions in

measurement-like situations are suppressed in very short times. Accordingly, as a consequence of the unified dynamics governing all physical processes, individual macroscopic objects acquire definite macroscopic properties. The choice suggested in the GRW-model is:

(5) $f = 10^{-16}\ s^{-1}$

$d = 10^{-5}$ cm

It follows that a microscopic system undergoes a localization, on average, every hundred million years, while a macroscopic one undergoes a localization every 10^{-7} seconds. With reference to the challenging version of the macro-objectification problem presented by Schrödinger with the famous example of his cat, J.S. Bell comments [Bell, 1987, p.44]: [within QMSL] *the cat is not both dead and alive for more than a split second* . Besides the extremely low frequency of the hittings for microscopic systems, also the fact that the localization width is large compared to the dimensions of atoms (so that even when a localization occurs it does very little violence to the internal economy of an atom) plays an important role in guaranteeing that no violation of well-tested quantum mechanical predictions is implied by the modified dynamics.

Some remarks are appropriate. First of all, QMSL, being precisely formulated, allows to locate precisely the ‘split’ between micro and macro, reversible and irreversible, quantum and classical. The transition between the two types of ‘regimes’ is governed by the number of particles which are well localized at positions further apart than 10^{-5} cm in the two states whose coherence is going to be dynamically suppressed. Second, the model is, in principle, testable against quantum mechanics. As a matter of fact, an essential part of the program consists in proving that its predictions do not contradict any established fact about microsystems and macrosystems.

6. The Continuous Spontaneous Localization Model (CSL)

The model just presented (QMSL) has a serious drawback: it does not allow to deal with systems containing identical constituents because it does not respect the symmetry or antisymmetry requirements for such particles. A quite natural idea to overcome this difficulty would be that of relating the hitting process not to the individual particles but to the particle number density averaged over an appropriate volume. However, incorporating this idea in the QMSL scheme would require the introduction of a new constant besides the two which already appear in the model.

A more satisfactory solution to this problem (see however the remarks at the end of this subsection) can be obtained by injecting the physically appropriate principles of the GRW model within the approach of P. Pearle. This line of thought has led to a quite elegant formulation of a dynamical reduction model, usually referred to as CSL [Pearle, 1989; Ghirardi, Pearle and Rimini, 1990] in which the discontinuous jumps which characterize QMSL are replaced by a continuous stochastic evolution in the Hilbert space (a

sort of Brownian motion of the statevector).

We will not enter into the rather technical details of this interesting development of the original GRW proposal, since the basic ideas and physical implications are precisely the same as those of the original formulation. Actually, one could argue that the above idea of tackling the problem of identical particles by considering the average particle number within an appropriate volume is correct. In fact it has been proved [Ghirardi, Pearle and Rimini, 1990] that for any CSL dynamics there is a hitting dynamics which, from a physical point of view, is 'as close to it as one wants'. Instead of entering into the details of the CSL formalism, it is useful, for the discussion below, to analyze a simplified version.

7. A Simplified Version of CSL

With the aim of understanding the physical implications of the CSL model, such as the rate of suppression of coherence, we make now some simplifying assumptions. First, we assume that we are dealing with only one kind of particles (e.g., the nucleons), secondly, we disregard the standard Schrödinger term in the evolution and, finally, we divide the whole space in cells of volume d^3. We denote by $|n_1, n_2, ... >$ a state in which there are n_i particles in cell i, and we consider a superposition of two states $|n_1, n_2, ... >$ and $|m_1, m_2, ... >$ which differ in the occupation numbers of the various cells of the universe. With these assumptions it is quite easy to prove that the rate of suppression of the coherence between the two states (so that the final state is one of the two and not their superposition) is governed by the quantity:

$$(6)\ \exp\{-f[(n_1 - m_1)^2 + (n_2 - m_2)^2 + ...]t\},$$

the sum being extended to all cells in the universe. Apart from differences relating to the identity of the constituents, the overall physics is quite similar to that implied by QMSL. Obviously, there are interesting physical implications which deserve to be discussed. A detailed analysis has been presented in [Ghirardi and Rimini, 1990]. As shown there and as follows from estimates about possible effects for superconducting devices [Rae, 1990; Gallis and Fleming, 1990; Rimini, 1995], and for the excitation of atoms [Squires, 1991], it turns out not to be possible, with present technology, to perform clear-cut experiments allowing to discriminate the model from standard quantum mechanics [Benatti *et al.*, 1995].

There is however an interesting aspect which might be relevant to idea of relating the suppression of coherence to gravitational effects. Given Eq. (6), notice that the worst case scenario (from the point of view of the time necessary to suppress coherence) is the superposition of two states for which the occupation numbers of the individual cells differ only by one unit. Indeed, in this case the amplifying effect of taking the square of the differences disappears. Let us then raise the question: how many nucleons (at worst) should occupy different cells, in order for the given superposition to be dynamically suppressed within the time which characterizes human perceptual processes? Since such a time is of the order of 10^{-2} sec and $f = 10^{-16}$ sec^{-1}, the number of displaced nucleons must be of the order of 10^{18}, which corresponds, to a remarkable accuracy, to a Planck mass. This figure seems to point in the same

direction as attempts such as Penrose's attempts to relate reduction mechanisms to quantum gravitational effects [Penrose, 1989].

8. Achievements of Collapse Theories

A. Pais famously recalls in his biography of Einstein:

> We often discussed his notions on objective reality. I recall that during one walk Einstein suddenly stopped, turned to me and asked whether I really believed that the moon exists only when I look at it [Pais, 1982, p. 5].

In the context of Einstein's remarks in *Albert Einstein, Philosopher-Scientist* [Schilpp, 1949], we can regard this reference to the moon as an extreme example of 'a fact that belongs entirely within the sphere of macroscopic concepts', as is also a mark on a strip of paper that is used to register the outcome of a decay experiment, so that

> as a consequence, there is hardly likely to be anyone who would be inclined to consider seriously [...] that the existence of the location is essentially dependent upon the carrying out of an observation made on the registration strip. For, in the macroscopic sphere it simply is considered certain that one must adhere to the program of a realistic description in space and time; whereas in the sphere of microscopic situations one is more readily inclined to give up, or at least to modify, this program [p. 671].

However,

> the 'macroscopic' and the 'microscopic' are so inter-related that it appears impracticable to give up this program in the 'microscopic' alone [p. 674].

One might speculate that Einstein would not have taken the DRP seriously, given that it is a fundamentally indeterministic program. On the other hand, the DRP allows precisely for this middle ground, between giving up a 'realistic description in space and time' altogether (the moon is not there when nobody looks), and requiring that it be applicable also at the microscopic level (as some kind of 'hidden variables' theory). It would seem that the pursuit of 'realism' for Einstein was more a program that had been very successful rather than an a priori commitment, and that in principle he would have welcomed attempts to give up or weaken microrealistic requirements, provided they allowed one to adopt a macrorealist position.

In the DRP, we can say of an electron in an EPR-Bohm situation that 'when nobody looks', it has no definite spin in any direction , and in particular that when it is in a superposition of two states localised far away from each other, it cannot be thought to be at a definite place. In the macrorealm, however, objects do have definite positions and are generally describable in classical terms. That is, the DRP

program is not adding ‘hidden variables’ to the theory, but the moon is definitely there even if no sentient being has ever looked at it, or, in the words of J. S. Bell, the DRP

> allows electrons (in general microsystems) to enjoy the cloudiness of waves, while allowing tables and chairs, and ourselves, and black marks on photographs, to be rather definitely in one place rather than another, and to be described in classical terms [Bell, 1986, p. 364].

Such a program, as we have seen, is realized by assuming only the existence of wave functions, and by proposing a unified dynamics that will govern both microscopic processes and ‘measurements’. As regards the latter, no vague definitions are needed in order to apply the theory. The equations are followed exactly, and the macroscopic ambiguities that would arise from the linear evolution are theoretically possible, but only of momentary duration, and thus arguably of no practical importance and no source of embarrassment.

We have not analyzed yet the implications about locality, but since in the DRP program no hidden variables are introduced, the situation can be no worse that in ordinary quantum mechanics: *‘by adding mathematical precision to the jumps in the wave function, it simply makes precise the action at a distance of ordinary quantum mechanics’* [Bell, 1987, p. 46]. Indeed, a detailed investigation of the locality properties of the theory becomes possible, and one can investigate whether the theory represents an approximation to a relativistically invariant theory. The analysis carried on so far, however, proves that at least in the non-relativistic version a program of dynamical reduction can be consistently developed. Moreover, as it will become clear when we will discuss the interpretation of the theory in terms of mass density, the QMSL and CSL theories lead in a natural way to attach definite properties in space and time to macroscopic objects, the main objective of Einstein’s requirements.

The achievements of the DRP which are relevant for the debate about the foundations of quantum mechanics can also be concisely summarized in the words of H.P. Stapp:

> The collapse mechanisms so far proposed could, on the one hand, be viewed as ad hoc mutilations designed to force ontology to kneel to prejudice. On the other hand, these proposals show that one can certainly erect a coherent quantum ontology that generally conforms to ordinary ideas at the macroscopic level [Stapp, 1989, p. 157].

9. Relativistic Dynamical Reduction Models

When confronted with a new theoretical scheme, particularly with one which, as we have seen [Bell, 1987], ‘makes precise the action at a distance of ordinary quantum mechanics’, one is naturally led to raise the question of whether it represents an approximation to a relativistically invariant theory. In this connection it is useful to mention, first of all, some interesting recent investigations of the non-local aspects of CSL.

As is well known, [Suppes and Zanotti, 1976; van Fraassen, 1982; Jarrett, 1984; Shimony, 1983; see also the entry on Bell's Theorem], Bell's locality assumption is equivalent to the conjunction of two other assumptions, viz., in Shimony's terminology, parameter independence and outcome independence. In view of the experimental violation of Bell's inequality, one has to give up either or both of these assumptions. The above splitting of the locality requirement into two logically independent conditions is particularly useful in discussing the different status of CSL and deterministic hidden variable theories with respect to relativistic requirements. In fact, as proved by Jarrett himself, when parameter independence is violated, if one had access to the variables which specify completely the state of individual physical systems, one could send faster-than-light signals from one wing of the apparatus to the other. Moreover, in ref. [Ghirardi and Grassi, 1994, 1996] it has been shown that it is impossible to build a genuine relativistically invariant theory which, in its nonrelativistic limit, exhibits parameter dependence and does not entail backward causation. On the other hand, if locality is violated only by the occurrence of outcome dependence then faster-than-light signaling cannot be achieved.

Now, it is well known that any deterministic theory (i.e., one in which the range of all probability distributions for outcomes is the set {0,1}) that reproduces quantum predictions must exhibit parameter dependence. This fact by itself suggest that such theories will certainly meet more serious difficulties with relativity than theories like standard quantum mechanics which violate only outcome independence and which do not allow faster-than-light signaling [Eberhard, 1978; Ghirardi, Rimini and Weber, 1980; Ghirardi, Grassi, Rimini and Weber, 1988]. What about CSL? It has been possible to prove [Ghirardi, Grassi, Butterfield and Fleming, 1993; Butterfield *et al*., 1993] that it, too, violates Bell's locality only by violating outcome independence. This is to some extent encouraging; even though, as we will be led to conclude, it seems extremely difficult to build a relativistic model inducing reductions, this result shows that there are no reasons of principle making such a project unviable.

Let us be more specific. The first attempt to obtain a relativistic generalization of dynamical reduction models was presented in ref. [Pearle, 1990]. It should be stressed that having individual reductions prevents the theory from being invariant at the individual level (note that QMSL and CSL are not even Galilei invariant at the individual level). Thus one is led to introduce a generalization of the invariance requirement: the theory must be stochastically invariant. This means that, even though the individual processes may look different to different observers, any two of them will agree on the composition of the final ensemble for (subjectively) the same initial conditions. We remark that it is precisely in this sense that both QMSL and CSL turn out to be Galilei invariant.

Pearle [1990] considered a fermion field coupled to a meson field and has put forward the idea of inducing localizations for the fermions through their coupling to the mesons and a stochastic dynamical reduction mechanism acting on the meson variables. He considered Heisenberg evolution equations for the coupled fields and a Tomonaga-Schwinger CSL-type evolution equation with a skew-hermitian coupling to a c-number stochastic potential for the state vector. This approach has been systematically investigated in refs. [Ghirardi, Grassi and Pearle, 1990a, 1990b] to which we refer the reader for a detailed discussion. Here we limit ourselves to stressing that, under certain approximations, one obtains in the non-relativistic limit a CSL-type equation inducing spatial localization. However, due to the white

noise nature of the stochastic potential, novel renormalization problems arise: the increase per unit time and per unit volume in the energy of the meson field is infinite due to the fact that infinitely many mesons are created. For the reasons we have just discussed one cannot say that the possibility of generalizing CSL to the relativistic case has been established. Not even more recent attempts have succeeded in overcoming these difficulties.

Nevertheless, the efforts which have been spent on such a program have led to a better understanding of some points and have thrown light on important conceptual issues. First, they have led to a completely general and rigorous formulation of the concept of stochastic invariance [Ghirardi, Grassi and Pearle, 1990a]. Second, they have prompted a critical reconsideration, based on the discussion of smeared observables with compact support, of the problem of locality at the individual level. This analysis has brought out the necessity of reconsidering the criteria for the attribution of objective local properties to physical systems. In specific situations, one cannot attribute any local property to a microsystem: any attempt to do so gives rise to ambiguities. However, in the case of macroscopic systems, the impossibility of attributing to them local properties (or, equivalently, the ambiguity surrounding such properties) lasts only for time intervals of the order of those necessary for the dynamical reduction to take place. Moreover, no objective property corresponding to a local observable, even for microsystems, can emerge as a consequence of a measurement-like event occurring in a space-like separated region: such properties emerge only in the future light cone of the macroscopic event considered. Finally, recent investigations [Ghirardi and Grassi, 1994, 1996; Ghirardi, 1996, 2000] have shown that the very formal structure of the theory is such that it does not allow, even conceptually, to establish cause-effect relations between space-like events.

Having listed some interesting results obtained along these lines, in concluding this section it is necessary to stress once more the immense difficulties that the program of a relativistic generalization has met until now. The question of whether such a program will find a satisfactory formulation still remains ‘the big problem’ for this type of investigations.

10. Collapse Theories and Definite Perceptions

Some authors [Albert and Vaidman, 1989; Albert, 1990, 1992] have raised an interesting objection concerning the emergence of definite perceptions within Collapse Theories. The objection is based on the fact that one can easily imagine situations leading to definite perceptions, that nevertheless do not involve the displacement of a large number of particles up to the stage of the perception itself. These cases would then constitute actual measurement situations which cannot be described by QMSL, contrary to what happens for the idealized (according to the authors) situations considered in QMSL, i.e. those involving the displacement of some sort of pointer. To be more specific, the above papers considered a ‘measurement’ process whose output is the emission of a burst of photons. This can easily be devised by considering, e.g., a Stern-Gerlach set-up in which the two paths followed by the microsystem according to the value of its spin component hit a fluorescent screen and excite a small number of atoms which subsequently decay, emitting a small number of photons. The argument goes as follows: since only a few atoms are excited, since the excitations involve displacements which are smaller than the characteristic

localization distance of QMSL, since QMSL does not induce reductions on photon states and, finally, since the photon states immediately overlap, there is no way for the spontaneous localization mechanism to become effective. The superposition of the states ‘photons emerging from point *A* of the screen’ and ‘photons emerging from point *B* of the screen’ will last for a long time. On the other hand, since the visual perception threshold is quite low (about 6-7 photons), there is no doubt that the naked eye of a human observer is sufficient to detect whether the luminous spot on the screen is at *A* or at *B*. The conclusion follows: in the case under consideration no dynamical reduction can take place and as a consequence no measurement is over, no outcome is definite, up to the moment in which a conscious observer perceives the spot.

We have presented a detailed answer to this criticism [Aicardi *et al*., 1991]. The crucial points of our argument are the following: we perfectly agree that in the case considered the superposition persists for long times (actually the superposition must persist, since, the system under consideration being microscopic, one could perform interference experiments which everybody would expect to confirm quantum mechanics). However, to deal in the appropriate and correct way with such a criticism, one has to consider all the systems which enter into play (electron, screen, photons and brain) and the universal dynamics governing all relevant physical processes. A simple estimate of the number of ions which are involved in the visual perception mechanism makes perfectly plausible that, in the process, a sufficient number of particles are displaced by a sufficient spatial amount to satisfy the conditions under which, according to QMSL, the suppression of the superposition of the two nervous signals will take place within the time scale of perception.

To avoid misunderstandings, this analysis by no means amounts to attributing a special role to the conscious observer or to perception. The observer’s brain is the only system present in the set-up in which a superposition of two states involving different locations of a large number of particles occurs. As such it is the only place where the reduction can and actually must take place according to the theory. It is extremely important to stress that if in place of the eye of a human being one puts in front of the photon beams a spark chamber or a device leading to the displacement of a macroscopic pointer, or producing ink spots on a computer output, reduction will equally take place. In the given example, the human nervous system is simply a physical system, a specific assembly of particles, which performs the same function as one of these devices, if no other such device interacts with the photons before the human observer does. It follows that it is incorrect and seriously misleading to claim that QMSL requires a conscious observer to make definite the macroscopic properties of physical systems.

A further remark may be appropriate. The above analysis could be taken by the reader as indicating a very naive and oversimplified attitude towards the deep problem of the mind-brain correspondence. There is no claim and no presumption that QMSL allows a physicalist explanation of conscious perception. It is only pointed out that, for what we know about the purely physical aspects of the process, one can state that before the nervous pulses reach the higher visual cortex, the conditions guaranteeing the suppression of one of the two signals are verified. In brief, a consistent use of the dynamical reduction mechanism in the above situation accounts for the definiteness of the conscious perception, even in the extremely peculiar situation devised by Albert and Vaidman.

11. The Interpretation of the Theory

As stressed in the opening sentences of this contribution, the most serious problem of standard quantum mechanics lies in its being extremely successful in telling us about *what we observe*, but being basically silent on *what is*. This specific feature is closely related to the probabilistic interpretation of the statevector, combined with the completeness assumption of the theory. Notice that what is under discussion is the probabilistic interpretation, not the probabilistic character, of the theory. Also collapse theories have a fundamentally stochastic character, but, due to their most specific feature, i.e. that of driving the statevector of any individual physical system into appropriate and physically meaningful manifolds, they allow for a different interpretation. In fact, one could say (if one wants to avoid that they too, as the standard theory, speak only of *what we find*) that they impose a different interpretation, one that accounts for our perceptions at the appropriate, i.e. macroscopic, level.

The question of the correct interpretation of the theory has been the subject of debate, some of the principal approaches having originated with J. S. Bell. Given that the wavefunction itself is an object in the (higher-dimensional) configuration space, Bell was particularly keen to identify what could be taken as some kind of ‘local beable’, from which one could obtain a representation of the perceived reality in ordinary three-dimensional space. In the specific context of QMSL, Bell [1987, p. 45] suggested that the ‘GRW jumps’, which we called ‘hittings’ above, could play this role. Later, he suggested that the most natural interpretation for the wavefunction in the context of a collapse theory would be as describing the ‘density [...] of stuff’ in configuration space [Bell, 1990, p. 30]. The interpretation which, in the opinion of the present writer, is most appropriate for collapse theories [Ghirardi, Grassi and Benatti, 1995, Ghirardi, 1997a, 1997b] was ultimately developed from this suggestion, together with the firm conviction that an acceptable interpretation should establish precise links between our formal description of physical processes and the events taking place in the three-dimensional space we ‘see’ around us.

First of all, various investigations [Pearle and Squires, 1994] had made clear that QMSL and CSL needed a modification, i.e., the characteristic localization frequency of the elementary constituents of matter had to be made proportional to the mass characterizing the particle under consideration. In particular, the original frequency for the hitting processes $f = 10^{-16}$ sec^{-1} is the one characterizing the nucleons, while, e.g., electrons would suffer hittings with a frequency reduced by about 2000 times. Unfortunately we have no space to discuss here the physical reasons which make this choice appropriate; we refer the reader to the above paper, as well as to the recent detailed analysis by Peruzzi and Rimini [Peruzzi and Rimini, 2000]. With this modification, what the nonlinear dynamics strives to make ‘objectively definite’ is the average mass distribution in the whole universe (averaged over appropriate volumes associated with the characteristic localization accuracy of the theory). Second, a deep critical reconsideration [Ghirardi, Grassi and Benatti, 1995] has made evident how the concept of ‘distance’ that characterizes the Hilbert space is inappropriate in accounting for the similarity or difference between macroscopic situations. Just to give a convincing example, consider three states |*h*>, |*h**> and |*t*> of a macrosystem (let us say a massive macroscopic bulk of matter), the first corresponding to its being located here, the second to its having the same location but one of its atoms (or molecules) being in a state orthogonal to the corresponding state in |*h*>, and the third having exactly the same internal state of the first but being

differently located (there). Then, despite the fact that the first two states are practically indistinguishable from each other at the macrolevel, while the first and the third correspond to completely different and directly perceivable situations, the Hilbert space distance between $|h\rangle$ and $|h^*\rangle$, is equal to that between $|h\rangle$ and $|t\rangle$.

When the localization frequency is related to the mass of the constituents, then, as above and completely generally (i.e. even when one is dealing with a body which is not almost rigid, such as a gas or a cloud), the mechanism leading to the suppression of the superpositions of macroscopically different states is fundamentally governed by the sum (or the integral) of the squared differences of the mass densities associated to the two superposed states, averaged over the characteristic volume of the theory, i.e., 10^{-15} cm^3 . This suggests taking the following attitude: what the theory is about, what is real ‘out there’ at a given space point **x**, is just the average mass density in the characteristic volume around **x** :

$$(7)\ M(\boldsymbol{x},t) = \langle F,t \mid M(\boldsymbol{x}) \mid F,t \rangle,$$

where $M(\boldsymbol{x})$ is the mass density operator corresponding to the given volume around $\boldsymbol{x}$ and $|F,t\rangle$ is the statevector characterizing the system at the given time. It is obvious that within standard quantum mechanics such a function cannot be endowed with any objective physical meaning due to the occurrence of linear superpositions of macroscopically different mass distributions which give rise to values that do not correspond to what we find in a measurement process or what we perceive (typically the equal weight superposition of the states $|h\rangle$ and $|t\rangle$ will give rise to a mass density distribution which is 1/2 of the actual one both ‘here’ and ‘there’). But in a CSL model relating reductions to mass density differences, the dynamics, as we have seen, suppresses in extremely short times these embarrassing superpositions. In this case, if one considers only the states allowed by the dynamics one can give a description of the world in terms of $M(\boldsymbol{x},t)$, i.e., one recovers a physically meaningful account of physical reality in the usual 3-dimensional space and time. Resorting to the quantity (7) one can also define an appropriate ‘distance’ between two states as the integral over the whole 3-dimensional space of the square of the difference of $M(\boldsymbol{x},t)$ for the two given states, a quantity which turns out to be perfectly appropriate to ground the concept of macroscopically similar or distinguishable Hilbert space states. In turn this distance can be used as a basis to define a sensible psychophysical correspondence within the theory.

12. The Problem of the Tails of the Wave Function

In recent years, there has been a lively debate around a problem which has its origin, according to some of the authors which have raised it, in the fact that even though the localization process, which corresponds to multiplying the wave function times a Gaussian, and thus leads to wave functions strongly peaked around the position of the hitting, it leads to wave functions that are different from zero over the whole of space. The first criticism of this kind was raised by A. Shimony [Shimony, 1990] and can be summarized by his sentence,

> one should not tolerate tails in wave functions which are so broad that their different parts can be discriminated by the senses, even if very low probability amplitude is assigned to them.

After a localization of a macroscopic system, typically the pointer of the apparatus, its centre of mass will be associated to a wave function which is different from zero over the whole space. If one adopts the probabilistic interpretation of the standard theory, this means that even when the measurement process is over, there is a nonzero (even though extremely small) probability of finding its pointer in an arbitrary position, instead of the one corresponding to the registered outcome. This is taken as inacceptable, as indicating that the DRP does not actually overcome the macro-objectification problem.

Let us state immediately that the (alleged) problem arises entirely from keeping the standard interpretation of the wave function unchanged, in particular assuming that its modulus squared gives the probability density of the position variable. However, as we have discussed in the previous section, there are much more serious reasons of principle which require to abandon the probabilistic interpretation and replace it either with one of those proposed by Bell, or, more appropriately in our opinion, with the mass density interpretation have outlined above.

Before entering into a detailed discussion of this subtle point we need to focus the problem better. We cannot avoid making two remarks. Suppose one adopts, for the moment, the conventional quantum position. We agree that, within such a framework, the fact that wave functions never have strictly compact spatial support can be considered puzzling. However this is a problem arising directly from the mathematical features (spreading of wave functions) and from the probabilistic interpretation of the theory, and not at all a problem peculiar to the dynamical reduction models. Indeed, the fact that, e.g., the wave function of the centre of mass of a pointer or of a table has not a compact support has never been taken to be a problem for standard quantum mechanics. When the wave function is extremely well peaked around a given point in space, it has always been accepted that it describes a table located at a certain position, and that this corresponds in some way to our perception of it. It is obviously true that, for the given wave function, the quantum rules entail that if a measurement were performed the table could be found (with an extremely small probability) to be kilometers far away, but this *is not* the measurement or the macro-objectification problem of the standard theory. The latter concerns a completely different situation, i.e., that in which one is confronted with a superposition with comparable weights of two macroscopically separated wave functions, both of which possess tails (i.e., have non-compact support) but are appreciably different from zero only in very narrow intervals. This is the really embarrassing situation which conventional quantum mechanics is unable to make understandable. To which perception of the position of the table does this wave function correspond?

The implications for this problem of the adoption of the QMSL theory should be obvious. Within QMSL, the superposition of two states which, when considered individually, are assumed to lead to different and definite perceptions of macroscopic locations, are dynamically forbidden. If some process tends to produce such superpositions, then the reducing dynamics induces the localization of the centre of mass (the associated wave function being appreciably different from zero only in a narrow and precise interval). Correspondingly, the possibility arises of attributing to the system the property of being in a

definite place and thus of accounting for our definite perception of it. Summarizing, we stress once more that the criticism about the tails as well as the requirement that the appearance of macroscopically extended (even though extremely small) tails be strictly forbidden is exclusively motivated by uncritically committing oneself to the probabilistic interpretation of the theory, even for what concerns the psycho-physical correspondence: states assigning non-exactly vanishing probabilities to different outcomes of position measurements must correspond to ambiguous perceptions about these positions. Since neither within the standard formalism nor within the framework of dynamical reduction models a wave function can have compact support, taking such a position leads to conclude that it is just the Hilbert space description of physical systems which has to be given up.

It ought to be stressed that there is nothing in the GRW theory which would make the choice of functions with compact support problematic for the purpose of the localizations, but it also has to be noted that following this line would be totally useless: since the evolution equation contains the kinetic energy term, any function, even if it has compact support at a given time, will instantaneously spread acquiring a tail extending over the whole of space. If one sticks to the probabilistic intepretation and one accepts the completeness of the description of the states of physical systems in terms of the wave function, the tail problem cannot be avoided.

The solution to the tails problem can only derive from abandoning completely the probabilistic interpretation and from adopting a more physical and realistic intepretation relating ‘what is out there’ to, e.g., the mass density distribution over the whole universe. In this connection, the following example will be instructive [Ghirardi, Grassi and Benatti, 1995]. Take a massive sphere of normal density and mass of about 1 kg. Classically, the mass of this body would be totally concentrated within the radius of the sphere, call it r. In QMSL, after the extremely short time interval in which the collapse dynamics leads to a ‘regime’ situation, and if one considers a sphere with radius $r + 10^{-5}$ cm, the integral of the mass density over the rest of space turns out to be an incredibly small fraction (of the order of 1 over 10 to the power 10^{15}) of the mass of a single proton. In such conditions, it seems quite legitimate to claim that the macroscopic body is localised within the sphere.

However, also this quite reasonable position has been questioned and it has been claimed [Lewis, 1997], that the very existence of the tails implies that the enumeration principle (i.e. the fact that the claim ‘particle 1 is within this box & particle 2 is within this box & ... & particle *n* is within this box & no other particle is within this box’ implies the claim ‘there are *n* particles within this box’) does not hold, if one takes seriously the mass density interpretation of collapse theories. This paper has given rise to a long debate which would be inappropriate to reproduce here. We refer the reader to the following papers [Ghirardi and Bassi, 1999; Clifton and Monton, 1999a, 1999b; Bassi and Ghirardi, 1999, 2001]. Various arguments have been presented in favour and against the criticism by Lewis.

We would like to conclude this brief analysis by stressing once more that, in our opinion, all the disagreements and the misunderstandings concerning this problem have their origin in the fact that the idea that the probabilistic interpretation of the wave function must be abandoned has not been fully accepted by the authors who find some difficulties in the proposed mass density intepretation of the

Collapse Theories.

Summary

We hope to have succeeded in giving a clear picture of the ideas, the implications, the achievements and the problems of the DRP. We conclude by stressing once more our position with respect to the Collapse Theories. Their interest derives entirely from the fact that they have given some hints about a possible way out from the difficulties characterizing standard quantum mechanics, by proving that explicit and precise models can be worked out which agree with all known predictions of the theory and nevertheless allow, on the basis of a universal dynamics governing all natural processes, to overcome in a mathematically clean and precise way the basic problems of the standard theory. In particular, the Collapse Models show how one can work out a theory that makes perfectly legitimate to take a macrorealistic position about natural processes, without contradicting any of the experimentally tested predictions of standard quantum mechanics.

Measurement in Quantum Theory

From the inception of Quantum Mechanics (QM) the concept of measurement has proved a source of difficulty. The Einstein-Bohr debates, out of which both the Einstein Podolski Rosen paradox and Schrödinger's cat paradox developed, centered upon this difficulty. The problem of measurement in quantum mechanics arises out of the fact that several principles of the theory appear to be in conflict. In particular, the dynamic principles of quantum mechanics seem to be in conflict with the postulate of collapse. David Albert puts the problem nicely when he says:

> The dynamics and the postulate of collapse are flatly in contradiction with one another ... the postulate of collapse seems to be right about what happens when we make measurements, and the dynamics seems to be bizarrely *wrong* about what happens when we make measurements, and yet the dynamics seems to be *right* about what happens whenever we *aren't* making measurements. (Albert 1992, 79)

This has come to be known as "the measurement problem" and in what follows, we study the details and examine some of the implications of this problem.

The measurement problem is not just an interpretational problem internal to QM. It raises broader issues as well, such more general philosophical debates between, on the one hand, Cartesian and Lockean accounts of observation as the creation of "inner reflections" and, on the other, neo-Kantean conceptions of observation as a quasi-externalized physiological process. In this article I trace the history of these debates, and indicate some of the interpretative strategies that they stimulated.

The Birth of the Measurement Problem

The measurement problem in QM (Quantum Mechanics) grew out of early debates over Niels Bohr's "Copenhagen interpretation". Bohr maintained that the physical properties of quantum systems depend in a fundamental way upon experimental conditions, including conditions of measurement. This doctrine appeared explicitly in Bohr's 1935 reply to Einstein, Podolski, and Rosen: "The procedure of measurement has an essential influence on the conditions on which the very definition of the physical quantities in question rests" (Bohr 1935, 1025; see too Bohr 1929). To be specific, Bohr endorsed the following principle:

> (P) If a quantity Q is measured in system S at time *t* then Q has a particular value in S at *t*.[1]

But, instead of taking the dependence of properties upon experimental conditions to be causal in nature, he proposed an analogy with the dependence of relations of simultaneity upon frames of reference postulated by special relativity theory: "The theory of relativity reminds us of the subjective [observer dependent] character of all physical phenomena, a character which depends essentially upon the state of motion of the observer" (Bohr 1929, 73). In general terms, then, Bohr proposed that, like temporal relations in special relativity, properties in QM exhibit a hidden relationalism - "hidden", that is, from a classical, Newtonian point of view. Paul Feyerabend gave a clear exposition of this Bohrian position in his "Problems of Microphysics" essay (Feyerabend, 1962). It can also be found in earlier commentaries upon Bohr by Vladimir Fock and Philip Frank (Jammer 1974, section 6.5).

Many of Bohr's colleagues, including his young *protege* Werner Heisenberg, misunderstood or rejected the relationalist metaphysics underpinning Bohr's endorsement of (P). Instead, they favored the positivistic, anti-metaphysical approach expressed in Heisenberg's influential book, *The Physical Principles of the Quantum Theory* (Heisenberg 1930): "It seems necessary to demand that no concept enter a theory which has not been experimentally verified at least to the same degree of accuracy as the experiments to be explained by the theory" (1).[2] On this view, (P) may be strengthened to the principle (P)′:

> (P)′ It is meaningless to assign Q a value *q* for S at *t* unless Q is measured to have value *q* for S at *t*.

Heisenberg's approach, as presented in *The Physical Principles of the Quantum Theory*, quickly became a popular way of reading (or misreading, as Bohr would claim) the philosophically more forbidding complexities of the Copenhagen interpretation. As Max Jammer points out: "It would be difficult to find a textbook of the period [1930-1950] which denied that the numerical value of a physical quantity has no meaning whatsoever until an observation has been performed" (Jammer 1974, 246).

Bohr disagreed with Heisenberg's extreme positivistic gloss of the Copenhagen interpretation that reduced questions of "definability to measurability" (Jammer 1974, 69). The disagreement was no casual matter. Heisenberg reports a discussion that arose while preparing his 1927 *Zeitschrift für Physik* paper in

the following terms: "I remember that it ended with my breaking out in tears because I just couldn't stand this pressure from Bohr" (Jammer 1974, 65). Nevertheless, the two men agreed in broad terms that ways of describing quantum systems depended upon experimental conditions. This agreement was sufficient to create at least the appearance of a unified Copenhagen position.[3]

The assumptions that framed the Bohr-Heisenberg interpretation were, in turn, rejected by Albert Einstein (Jammer 1974, chap.5; see too Bohr 1949). Einstein's disagreement with the Copenhagen school came to a head in the famous exchange with Bohr at the fifth Solvay conference (1927) and in the no less famous Einstein, Podolski, Rosen paper of 1935. Arguing from what might be called a "realist" position, Einstein contended that under ideal conditions observations (and measurements more generally) function like "mirrors" (or, as Crary argues, camera obscura) reflecting an independently existing reality (Crary 1995, 48). In particular, in the Einstein, Podolski, Rosen paper, we find the following criterion for the existence of physical reality: "If without in any way disturbing a system we can predict with certainty...the value of a physical quantity, then there exists an element of physical reality corresponding to this physical quantity" (Einstein et al 1935, 778). This criterion characterizes physical reality in terms of objectivity, meaning its independence from any direct measurement. By implication, then, when a direct measurement of physical reality occurs it merely passively reflects rather than actively constituting that which is observed.

Einstein's position has roots in Cartesian as well as empiricist, and specifically Lockean, notions of perception. This realist position opposes the Kantian metaphor of the "veil of perception" that pictures the apparatus of observation as like a pair of spectacles through which a highly mediated sight of the world can be glimpsed. To be specific, according to Kant, rather than simply reflecting an independently existing reality, "appearances" are constituted through the act of perception in a way that conforms them to the fundamental categories of sensible intuition. As Kant made the point in the Transcendental Aesthetic: "Not only are the drops of rain mere appearances, but...even their round shape, and even the space in which they fall, are nothing in themselves, but merely modifications of fundamental forms of our sensible intuition, and...the transcendental object remains unknown to us" (Kant 1973, 85).

By contrast, the realism that I am associating with Einstein takes the point of view that, insofar as they are real, when we observe rain drops under ideal conditions we are seeing objects "in themselves", that is, as they exist independently of being perceived. In other words, not only do the rain drops exist independently of our observations but also, in observing them, what we see reflects how they really are. In William Blake's succinct formulation, "As the eye [sees], such the object [is]" (Crary 1995, 70). According to this "realist" point of view, ideal observations not only reflect the way things are during but also immediately before and after observation.[4]

Such realism was opposed by both Bohr and Heisenberg.[5] Bohr took a position that, by taking acts of observation and measurement more generally as constitutive of phenomena, aligned him more closely with a Kantian point of view. To be specific, Bohr took it that "measurement has an essential [by which I take him to mean constitutive] influence on the conditions on which the very definition of the physical quantities in question rests" (Bohr 1935, 1025).

As Henry Folse points out, however, it is misleading to take the parallel between Bohr and Kant too far (Folse 1985, 49 and 217-221). Bohr strongly opposed the Kantian position that "space and time as well as cause and effect had to be taken as *a priori* categories for the comprehension of all knowledge" (Folse 1985, 218). This opposition between Bohr and Kant reflected a deeper division. Whereas for Kant "concepts played their role prior to experience and give form to what is experienced" (Folse, 220), for Bohr it was the other way around, that is, objective reality, in particular conditions of observation, determine the applicability of concepts. Thus, although for Bohr no less than for Kant, observation took on a role in determining the forms that structure the world of visible objects, the two men conceived the way in which that role is discharged quite differently. For Kant subjective experience was structured in terms of certain prior forms, whereas Bohr argued for a hidden relationalism in the domain of appearances, contending that the properties in terms of which a system is described are relative to the conditions of measurement.

This difference between Bohr and Kant may be seen as an aspect, indeed radicalization, of a more general shift in nineteenth century conceptions of vision, exemplified in Johannes Müller's compendious summary of current physiology, *Handbuch der Physiologie des Menschen* (1833). Müller (a mentor of the influential physicist Hermann von Helmholtz) may be seen as physiologizing the Kantian conception of observation. As Jonathon Crary makes the point:

> His [Müller's] work, in spite of his praise of Kant, implies something quite different. Far from being apodictic or universal in nature, like the ‘spectacles’ of time and space, our physiological apparatus is again and again shown to be defective, inconsistent, prey to illusion, and, in a crucial manner, susceptible to external procedures of manipulation and stimulation that have the essential capacity *to produce experience for the subject*.(Crary 1995, 92)

Crary implies here that during the nineteenth century observation, and specifically vision, were both reconceptualized not as a Kantian universal faculty but rather as physiological processes. In particular, it was assumed that observable phenomena were conditioned, not by universal forms of sensible intuition, but rather by the sorts of external physical factors that affected bodily and specifically physiological processes in general.

Bohr extended the nineteenth century concept by proposing that the "external procedures" that influence vision affect not only how we see but also the scientific concepts in terms of which what we see should be described. Even more radically, Bohr proposed that the "external procedures" that affect sensible intuitions include the processes of observation themselves. Thus Bohr stood at the end of a long historical trajectory. Both Kant and Descartes conceived the apparatus of observation as an inner mental faculty, analogous to a pair of spectacles (Kant) or a camera obscura (Descartes) mobilizing the perceptions of some inner Eye. In the nineteenth century, vision was projected outwards, reconceived as a bodily, and specifically physiological process (Müller, Helmholtz, and Johann Friedrich Herbart, Kant's successor at Königsberg). Bohr, then, completed the process of externalization by severing observation from the body, including it as one among many "external procedures" that affect accounts of what we see.[6]

Like Bohr, Heisenberg opposed Einstein's "realism". But whereas Bohr's opposition was rooted in a neo-Kantian relationalism that reversed Kant by externalizing the inner mental faculties, Heisenberg opposed Einstein from a more straightforwardly positivistic standpoint that disagreed not only with Einstein but also with Bohr.[7]

To be specific, Heisenberg took as meaningless the sorts of metaphysical speculations about the "true nature of reality" that preoccupied both Einstein and Bohr, speculations that, according to Heisenberg, betrayed their metaphysical nature by divorcing questions of truth from more concrete issues of what is observed:

> It is possible to ask whether there is still concealed behind the statistical universe of perception a ‘true’ universe in which the law of causality would be valid. But such speculation seems to us to be without value and meaningless, for physics must confine itself to the description of the relationship between perceptions.(Heisenberg 1927, 197)

The End of Copenhagen Monocracy

By embedding QM within the formal theory of Hilbert spaces, John von Neumann, a brilliant pure mathematician, provided the first rigorous axiomatic treatment of QM (von Neumann 1955 - the original German edition of this book appeared in 1932). Unlike Bohr and Einstein, he took seriously QM's formalism, not only providing the theory with rigorous mathematical foundations but also allowing a new conceptual architectonic to emerge from within the theory itself rather than following Heisenberg, Bohr, and Einstein who imposed a system of concepts *a priori*.

Von Neumann also intervened decisively into the measurement problem. Summarizing earlier work, he argued that a measurement on a quantum system involves two distinct processes that may be thought of as temporally contiguous stages (417-418).[8] In the first stage, the measured quantum system S interacts with M, a macroscopic measuring apparatus for the physical quantity Q. This interaction is governed by the linear, deterministic Schrödinger equation, and is represented in the following terms: at time t, when the measurement begins, S, the measured system, is in a state represented by a Hilbert space vector f that, like any vector in the Hilbert space of possible state vectors, is decomposable into a weighted sum - a "linear superposition" - of the set of so-called "eigenvectors" $\{f_i\}$ belonging to Q. In other words, $f = \Sigma c_i f_i$, for some set $\{c_i\}$ of complex numbers. f_i, the eigenvector of Q corresponding to possible value q_i, is that state of S at t for which, when S is in that state, there is unit probability that Q has value q_i.[9] M, the measuring apparatus, is taken to be in a "ready" state g at time t when the measurement begins. According to the laws of QM, this entails that S+M at t is in the "tensor product" state $\Sigma c_i f_i \otimes g$.

By applying the Schrödinger equation to this product state, we deduce that at time t', when the first stage of the measurement terminates, the state of S+M is $\Sigma c_i f_i \otimes g_i$, where g_i is a state in which M registers the value q_i.[10] Such states, represented by a linear combination of products of the form $f_i \otimes g_i$, have been

dubbed "entangled states".[11]

After the first stage of the measurement process, a second non-linear, indeterministic process takes place, the "reduction of the wave packet", that involves S+M "jumping" (the famous "quantum leap") from the entangled state $\Sigma c_i f_i \otimes g_i$ into the state $f_i \otimes g_i$ for some i. This, in turn (according to the laws of QM) means that S is in state f_i and M is in the state g_i, where g_i, it is assumed, is the state in which M registers the value q_i. Let t'' denote the time when this second and final stage of the measurement is finished.[12] It follows that at t'', when the measurement as a whole terminates, M registers the value q_i. Since the reduction of the wave-packet is indeterministic, there is no possibility of predicting which value M will register at t''. We can conclude only that M will register some value.

The second stage of the measurement, with its radical, non-linear discontinuities, was from its introduction the source of many of the philosophical difficulties that plagued QM, including what von Neumann referred to as its "peculiar dual nature" (417). As Schrödinger was moved to say during a visit to Bohr's institute during September 1926: "If all this damned quantum jumping [*verdamnte Quantenspringerei*] were really to stay, I should be sorry I ever got involved with quantum theory" (Jammer 1974, 57)

QM has nothing else definite to say about the measurement process. To be specific, from within the resources of QM there is no way of predicting what value of Q will be registered. QM does, however, give us some additional *statistical* information, via the so called Born statistical interpretation:

> The probability of q_i being registered is $|c_i|^2$, where $_i$ is the coefficient of f_i (the eigenvector of Q corresponding to value q_i) when the initial measured state of S is expressed as a linear superposition of eigenvectors of Q.

In short, QM does not predict what the measured value will be but does at least tells us the probability distribution over various possible measured values.

Cats in Singlets

Von Neumann's formal work enables a clear exposition of various paradoxes that have haunted QM from its inception. One of these was the famous Schrödinger cat paradox (Schrödinger 1935b). This paradox dramatizes the fact that, according to QM, the observer's intervention at the end of the first stage of the measurement process precipitates S+M from a complex entangled state, that is from a superposition or hybrid of states for which M registers different possible values for Q, into a state for which M registers a single value. In short, the act of observation creates a paradoxical shift in M: from a hybrid state for which the value that M registers is "indeterminate" to a state in which M registers precisely one such value. In the case of the cat paradox, matters are so arranged that a cat being dead or alive corresponds to the differing states of M. Thus, it seems, the act of observing the cat precipitates it from a strange zombie-

like state in which its state of morbidity is indeterminate to a state in which it is either dead or alive. "Looks can kill", as we might say.

The measurement problem was exacerbated by another paradox that arose in the context of the Einstein-Bohr debate: what has come to be called the EPR (Einstein-Podolski-Rosen) paradox (Einstein, Podolski, Rosen 1935). It should be stressed that in their original article EPR presented their argument as proof of the incompleteness rather than inconsistency of QM. Nevertheless, in the subsequent literature their argument quickly took on the role of a paradox, one that is most perspicuously presented in terms of the formalism developed by Bohm and Aharanov (Bohm and Aharanov 1957). Consider a pair of electrons S_1, S_2 at time *t* when they are in a so-called singlet state, represented by the vector

$$\{(f_{x+} \otimes g_{x-}) + (f_{x-} \otimes g_{x+})\}/\sqrt{2},$$

where f_{x+} and f_{x-} represent the two possible eigenstates of the x-directed spin of S_1 corresponding to the two possible spin values +1/2 and -1/2 respectively; g_{x-} and g_{x+} represent the corresponding eigenstates for S_2. From the Born statistical interpretation it is easy to deduce that when S_1+S_2 is in the singlet state, the x-spin values of S_1 and S_2 are anticorrelated, that is, the conditional probability of measuring the x-spin of S_1 to have value +1/2 given that the x-spin of S_2 is measured to have value -1/2 is 1, and vise versa. It is also a theorem of QM that the linear decomposition of the singlet state vector is invariant under rotation and in particular invariant under interchange of *x* and *y*:

$$(f_{x+} \otimes g_{x-}) + (f_{x-} \otimes g_{x+}) = (f_{y+} \otimes g_{y-}) + (f_{y-} \otimes g_{y+})$$

Now suppose that S_1 and S_2 have been allowed to drift out of each other's spheres of influence, so that a disturbance of S_1 can have no simultaneous effect upon S_2. Suppose too that we measure the *x*-spin of S_1 just before t, and that the value revealed by measurement is +1/2. In that case, the anti-correlation between the *x*-spin values for S_1 and S_2 makes it possible to predict with certainty that, in the event that the *x*-spin of S_2 is measured just before t, the value revealed by measurement is -1/2. The possibility of making this prediction means that the *x*-spin measurement on S_1 also counts as an *x*-spin measurement on S_2, albeit an indirect measurement since it is carried out in a region of space remote from S_2. By applying the reduction of the wave-packet postulate to this indirect measurement, we conclude that, at time t immediately after the measurement, the state of S_2 is g_{x-}, the eigenvector of *x*-spin for value -1/2.

But now assume that a second measurement has been carried out just before *t*, one that *directly* measures the spin of S_2 in the y direction. There is no difficulty in simultaneously conducting both of these measurements since, because they take place in different regions of space, they cannot interfere with each other. By applying the reduction of the wave-packet postulate to this second measurement, we conclude that the state of S_2 immediately post-measurement is either g_{y-} or g_{y+}, depending on whether the measured value for *y*-spin is -1/2 or +1/2. Thus we arrive at a direct contradiction, since the state of S_2

post-measurement cannot be both g_{x-} and one of g_{y-} or g_{y+}. Here, then, lies the nub of the EPR paradox, showing that QM is inconsistent with the reduction of the wave-packet postulate. (In its original form the EPR argument merely showed that without the reduction of the wave-packet postulate, QM is incomplete.[13])

The World of Many Interpretations

The measurement problem and its associated paradoxes have generated a multitude of responses. One such, based upon von Neumann's work with density operators, is due to Josef M. Jauch (Jauch 1968, chapter 11). The post measurement entangled state of S+M, $\Sigma c_i f_i \otimes g_i$, is a "pure state", represented by a single Hilbert space vector. There are, however, other sorts of states in QM, namely "mixed states", represented not by single vectors but rather by so called density operators. It is characteristic of S being in a mixed state that, from the point of view of statistical distributions over possible results of measurements on S, S behaves as if, for some set of vectors $\{f_i\}$ and some set of numbers $\{p_i\}$ for which $\Sigma p_i = 1$, there is probability p_i that S is in the state f_i, for i = 1,2,.... (Mathematically, such a state is represented by a so-called density operator, $\Sigma p_i \mid f_i\rangle\langle f_i \mid$, where $\mid f_i\rangle\langle f_i \mid$ is the projection operator onto the vector f_i.[14]) Von Neumann proved that when S+M is in the entangled state $\Sigma c_i f_i \otimes g_i$ then S is in such a mixed state. In particular, S behaves as if there were probability $|c_i|^2$ of being in state f_i, for i = 1,2...; similarly M is in a mixed state, behaving as if there were probability $|c_i|^2$ of being in state g_i, for i = 1,2....(von Neumann 1955, 424).

It seems, then, that a solution to the measurement problem is within easy reach. We simply interpret the state of S when S+M is in the entangled state $\Sigma c_i f_i \otimes g_i$ as a new sort of "mixed" state in which there really is probability $|c_i|^2$ that S is in the state f_i, for i = 1,2,.... The probability in question is not merely a subjective measure of ignorance (otherwise the state is really a pure state, as defined in the previous endnote) but instead is an "intrinsic" property of the system S, in particular, it may be thought of as an objective measure of a propensity of S at t to be in the state f_i (Jauch 1968, 173-174). This, in turn, means that, already at the end of the first stage of the measurement, there is probability $|c_i|^2$ that Q has value q_i in S (as above I am taking f_i as the eigenvector of Q corresponding to value q_i). By parity of reasoning, at the end of the first stage of the measurement, there is probability $|c_i|^2$ of M being in state g_i and hence of registering the value q_i for Q. Thus, it seems, the "reduction of the wave packet" is redundant, since already at the end of the first stage measurement the measuring apparatus registers the appropriate possible values with probabilities in agreement with the Born statistical interpretation. As such, those paradoxes of QM, such as EPR and Schrödinger's cat, that depend upon the reduction of the wave packet simply disappear.[15]

But a difficulty remains. The state of S+M at the end of measurement is still an entangled state for which, it seems, we cannot say that Q has value q_i with probability $|c_i|^2$. Indeed, from the perspective of that

combined state, it seems that the value of Q is indeterminate, suspended between the various possible values q_1, q_2, and so on. More seriously, it seems that the measuring apparatus suffers from a similar indeterminacy: that is, it is indeterminate which value it registers. In short, it seems that, from the point of view of the combined measuring and measured system, Schrödinger's cat paradox (although not his cat) survives unscathed.[16]

The Italian School of Daneri, Loinger, Prosperi, *et al* responded to this problem by advancing what has come to be called a "phase wash out" theory (Daneri, Loinger and Prosperi 1962). They showed that in virtue of statistical thermodynamic features of the measuring apparatus, the state of S+M at t' (the end of the first stage of measurement) approximates a mixed state - also called the "reduced state" - in which there is probability $|c_i|^2$ that S+M is in the state represented by the product vector $f_i \otimes g_i$, for all the various i = 1,2,..... In this reduced state the nagging indeterminacy effects vanish.

A serious difficulty remains, however. It may well be true that S+M is approximately in a mixed state. But this does not solve the cat paradox. That is, although it may be true that to a good approximation Schrödinger's cat is either dead or alive, the air of paradox remains if, when we examine in detail the micro-correlations between the measured and measuring systems, we see that the cat is in a zombie like dead-and-alive state.

The "phase wash out" approach and Jauch's approach more generally suffer another drawback, one they share with hidden variable interpretations of QM (for a discussion of the latter interpretations, see Belinfante 1973). In the special situation described by the EPR paradox, for which the density operator of the measured system is an identity operator, these interpretations assign determinate values to *all* physical quantities for a particular quantum system.[17] Thus they fall prey to a new generation of paradoxes that depend upon Gleason's theorem and the related Kochen and Specker theorem.[18]

The paradoxes and questions raised by the measurement problem have spawned a host of interpretations of QM, including hidden variable theories that continue Einstein's search for a "complete" account of physical reality, and the Everett-Wheeler "many worlds interpretation" (Wheeler and Zureck 1983, II.3 and III.3; Bell 1987, chapters 4 and 20). Most physicists bypass these philosophical resolutions of the interpretative difficulties of QM, and revert instead to some version of the Bohr interpretation. Often that version is related closely to the early Heisenberg's positivistic, anti-metaphysical approach. It is as if the long history of failure to resolve the acrimonious disputes surrounding the interpretation of QM has led quantum physicists to become disenchanted with the garden of metaphysical delights. As John S. Bell has made the point, despite more than seventy years of interpreting QM and resolving the measurement problem, the Bohr interpretation in its more pragmatic, less metaphysical forms remains the "working philosophy" for the average physicist (Bell 1987, 189).[19]

Notes to Quantum Theory

Notes

1. The issue of whether measurement was also a necessary condition for the assignment of values to physical quantities remained a question of controversy within the Copenhagen school. Bohr seems *not* to have insisted on this. Heisenberg, by contrast, at least in his early positivistic writings, seems committed to strengthening (P) so that measurement is both necessary and sufficient for the assignment of a determinate value to a physical quantity. I discuss this difference later.

2. Heisenberg discarded this positivistic approach in his later work, indeed, as early as 1930, according to Jammer (Jammer 76).

3. The question of Bohr's and Heisenberg's attitudes to positivism is a complex one. At least initially, in the context of their debate with Einstein they took common cause in favor of positivism (Jammer 1974, 109). As indicated in the previous footnote, however, Heisenberg quickly abandoned his earlier positivism, whereas, according to Beller and Fine, Bohr moved towards a more positivistic attitude in his later work (Beller and Fine 1994). On the issue of a unified "Copenhagen Spirit", see Beller 1996.

4. In more recent times, Popper and Bunge have been exponents of the Einsteinian position in the context of QM (Popper 1982, 35-41; Bunge 1967, 274-287). This position does not rule out the possibility of observations that fail to report what exists before or after their occurrence. But such observations, it is held, are defective. As one might say pejoratively, they present a "distorted" image of what we observe.

5. Indeed, it took them somewhat by surprise in the light of Einstein's early Machian position (Jammer 1974, 109).

6. Von Neumann's awkward attempt to rescue the internal status of observation, by talking about the arbitrariness of the *Schnitt* (cut) between observer and observed, may be understood as a reluctant acceptance of this Bohrian impoverishment of the "inner" life of the observer (von Neumann 1955, 418-420).

7. But see Beller and Fine 1994.

8. Von Neumann himself did not present these processes as temporally ordered stages, referring instead to the "peculiar dual nature of the quantum mechanical procedure" (417).

9. For simplicity I am assuming physical quantities with discrete spectra and one eigenvector for each possible value, that is, I am assuming a Hilbert space representation for Q as non-degenerate.

10. g_i may be thought of as a state for which a pointer that is part of M points to the i-th interval on a scale. Araki and Yanase have shown that such interactions are subject to very strong restrictions (Araki and Yanase 1960). Their work suggests that some weakening of the idealized form of measurement interaction is required.

11. Schrödinger seems to have been the first to suggest the term "entangled" in this context - see Schrödinger 1935a.

12. Note that it is not clear whether this second stage of the measurement process is instantaneous, that is whether $t'' > t'$ or $t'' = t'$. In part this reflects an ambiguity present in von Neumann's formulation of the problem, namely whether the two parts of the measurement should be seen as taking place simultaneously or as succeeding stages.

13. The version of the EPR paradox which I give here is close to the one reported in appendix *xii to Popper's *Logic of Scientific Discovery* (Popper 1968). It is taken from a letter by Einstein to Popper written in 1935, after publication of the EPR paper.

14. The more usual sorts of states of QM - the "pure states" - may be thought as degenerate cases of mixed states, that is, as mixed states for which $\{p_i\}$ is a singleton set, consisting of the number 1. In other words, a pure state is simply a mixed state for which there is unit probability that the system in question is in the state f, for some vector f.

15. Jauch 1968, 188-191. This interpretation also has the formal advantage that the Born statistical interpretation emerges as a theorem rather than being postulated as an independent axiom. This is because after measurement M is in a mixed state for which there is probability c_i^2 of M registering value q_i.

16. Jauch attempts to address this problem in terms of his theory of equivalent states - Jauch 1968, 184.

17. This is because the identity operator is multiply diagonalizable, that is, it is equal to $f_i >< f_i/N$ for any complete orthonormal set of vectors $\{f_i\}$, where N is the dimension of the Hilbert space.

18. For a discussion of these difficulties see Krips 1990, and Redhead 1987.

19. I am grateful to the editor, Rob Clifton, for his helpful comments.

Experiment in Physics

Physics, and natural science in general, is a reasonable enterprise based on valid experimental evidence, criticism, and rational discussion. It provides us with knowledge of the physical world and it is experiment that provides the evidence that grounds that knowledge. Experiment plays many roles in science. One of its important roles is to test theories and to provide the basis for scientific knowledge.[*/] It can also call for a new theory, either by showing that an accepted theory is incorrect, or by exhibiting a new phenomenon which needs explanation. Experiment can provide hints toward the structure or mathematical form of a theory and it can provide evidence for the existence of the entities involved in our theories. Finally, it may also have a life of its own, independent of theory. Scientists may investigate a phenomenon just because it looks interesting. This will also provide evidence for a future theory to explain. [Examples of these different roles will be presented below.] As we shall see below, a single experiment may play several of these roles at once.

If experiment is to play these important roles in science then we must have good reasons to believe experimental results, for science is a fallible enterprise. Theoretical calculations, experimental results, or the comparison between experiment and theory may all be wrong. Science is more complex than "The scientist proposes, Nature disposes." It may not always be clear what the scientist is proposing. Theories often need to be articulated and clarified. It also may not be clear how Nature is disposing. Experiments may not always give clear-cut results, and may even disagree for a time.

In what follows, the reader will find an epistemology of experiment, a set of strategies that provides reasonable belief in experimental results. Scientific knowledge can then be reasonably based on these experimental results.

I. Experimental Results

A. The Case For Learning From Experiment

1. An Epistemology of Experiment

It has been almost two decades since Ian Hacking asked, "Do we see through a microscope?" (Hacking 1981). Hacking's question really asked how do we come to believe in an experimental result obtained with a complex experimental apparatus? How do we distinguish between a valid result[1] and an artifact created by that apparatus? If experiment is to play all of the important roles in science mentioned above and to provide the evidential basis for scientific knowledge, then we must have good reasons to believe in those results. Hacking provided an extended answer in the second half of *Representing and Intervening* (1983). He pointed out that even though an experimental apparatus is laden with, at the very least, the theory of the apparatus, observations remain robust despite changes in the theory of the apparatus or in the theory of the phenomenon. His illustration was the continuous belief in microscope images despite the major change in the theory of the microscope when Abbe pointed out the importance of diffraction in its operation. One reason Hacking gave for this is that in making such observations the experimenters intervened. They manipulated the object under observation. Thus, in looking at a cell through a microscope one might inject fluid into the cell or stain the specimen. One expects the cell to change shape or color when this is done. Observing the predicted effect strengthens our belief in both the proper operation of the microscope and in the observation. This is true in general. Observing the predicted effect of an intervention strengthens our belief in both the proper operation of the experimental apparatus and in

the observations made with it.

Hacking also discussed the strengthening of one's belief in an observation by independent confirmation. The fact that the same pattern of dots, dense bodies in cells, is seen with "different" microscopes, i.e. ordinary, polarizing, phase-contrast, fluorescence, interference, electron, acoustic etc., argues for the validity of the observation. One might question whether or not "different" is theory laden. After all, it is our theory of light and of the microscope that allows us to consider these microscopes "different." Nevertheless, the argument goes through. Hacking correctly argues that it would be a preposterous coincidence if the same pattern of dots were produced in two totally different kinds of physical systems. Different apparatuses have different backgrounds and systematic errors, making the coincidence, if it is an artifact, most unlikely. If it is a correct result, and the instruments are working properly, the coincidence of results is understandable.

Hacking's answer is correct as far as it goes. It is, however, incomplete. What happens when one can perform the experiment with only one type of apparatus, such as an electron microscope or a radio telescope, or when intervention is either impossible or extremely difficult? Other strategies are needed to validate the observation.\2/ These may include:

> 1) Experimental checks and calibration, in which the experimental apparatus reproduces known phenomena. For example, if we wished to argue that the spectrum of a substance obtained with a new type of spectrometer is correct, we might check that this new spectrometer could reproduce the known Balmer Series in hydrogen. If we correctly observe the Balmer Series then we strengthen our belief that the spectrometer is working properly. This also strengthens our belief in the results obtained with that spectrometer. If the check fails then we have good reason to question the results obtained with that apparatus.
>
> 2) Reproducing artifacts that are known in advance to be present. An example of this comes from experiments to measure the infrared spectra of organic molecules (Randall et al. 1949). It was not always possible to prepare a pure sample of such material. Sometimes one had to place the substance in an oil paste or in solution. In such cases, one expects to observe, superimposed on the spectrum of the substance, the spectrum of the oil or the solvent, which one can compare with the known spectrum of the oil or the solvent. Observation of this artifact gives confidence in other measurements made with the spectrometer.
>
> 3) Elimination of plausible sources of error and alternative explanations of the result (the Sherlock Holmes strategy).\3/ Thus, when scientists claimed to have observed electric discharges in the rings of Saturn, they argued for their result by showing that it could not have been caused by defects in the telemetry, by interaction with the environment of Saturn, by lightning, or by dust. The only remaining explanation of their result was that it was due to electric discharges in the rings. There was no other plausible explanation of the

observation. In addition, the same result was observed by both Voyager 1 and Voyager 2. This provided independent confirmation. Often, several epistemological strategies are used in the same experiment.

4) Using the results themselves to argue for their validity. Consider the problem of Galileo's telescopic observations of the moons of Jupiter. Although one might very well believe that his early telescope might have created spots of light, it would have been extremely implausible that the telescope would create them so that they would appear to be a small planetary system with eclipses and other consistent motions. It would have been even more implausible to believe that the created spots would satisfy Kepler's Third Law (R^3/T^2 = constant). A similar argument was used by Robert Millikan to support his observation of the quantization of electric charge and his measurement of the charge of the electron. Millikan remarked, "The total number of changes which we have observed would be between one and two thousand, and *in not one single instance has there been any change which did not represent the advent upon the drop of one definite invariable quantity of electricity or a very small multiple of that quantity*"(Millikan 1911, p. 360). In both of these cases one is arguing that there was no plausible malfunction of the apparatus, or background, that would explain the observations.

5) Using an independently well-corroborated theory of the phenomena to explain the results. This was illustrated in the discovery of the $W^{\pm}$, the charged intermediate vector boson required by the Weinberg-Salam unified theory of electroweak interactions. Although these experiments used very complex apparatuses and used other epistemological strategies (see (Franklin 1986, pp. 170-72) for details) I believe that the agreement of the observations with the theoretical predictions of the particle properties helped to validate the experimental results. In this case the particle candidates were observed in events that contained an electron with high transverse momentum and in which there were no particle jets, just as predicted by the theory. In addition, the measured particle mass of 81 ± 5 GeV/c^2 and 80^{+10}_{-6}, GeV/c^2, found in the two experiments (note the independent confirmation also), was in good agreement with the theoretical prediction of 82 ± 2.4 GeV/c^2. It was very improbable that any background effect, which might mimic the presence of the particle, would be in agreement with theory.

6) Using an apparatus based on a well-corroborated theory. In this case the support for the theory passes on to the apparatus based on that theory. This is the case with both the electron microscope and the radio telescope, whose proper operation is based on a well-supported theory, although other strategies are also used to validate the observations.

7) Using statistical arguments. An interesting example of this arose in the 1960s when the search for new particles and resonances occupied a substantial fraction of the time and effort of those physicists working in experimental high-energy physics. The usual technique was to plot the number of events observed as a function of the invariant mass of

> the final-state particles and to look for bumps above a smooth background. The usual informal criterion for the presence of a new particle was that it resulted in a three standard-deviation effect above the background, a result that had a probability of 0.27% of occurring in a single bin. This criterion was later changed to four standard deviations, which had a probability of 0.0064% when it was pointed out that the number of graphs plotted each year by high-energy physicists made it rather probable, on statistical grounds, that a three standard-deviation effect would be observed.

These strategies along with Hacking's intervention and independent confirmation constitute an epistemology of experiment. They provide us with good reasons for belief in experimental results, They do not, however, guarantee that the results are correct. There are many experiments in which these strategies are applied, but whose results are later shown to be incorrect (examples will be presented below). Experiment is fallible.

2. Galison's Elaboration

In *How Experiments End* (1987), Peter Galison extended the discussion of experiment to more complex situations. In his histories of the measurements of the gyromagnetic ratio of the electron, of the discovery of the muon, and of the discovery of weak neutral currents, he considered a series of experiments measuring a single quantity, a set of different experiments culminating in a discovery, and two high energy physics experiments performed by large groups with complex experimental apparatus.

Galison's view is that experiments end when the experimenters believe that they have a result that will stand up in court. A result that I believe will include, and has included, the use of the epistemological strategies discussed earlier. Thus, David Cline, one of the weak neutral current experimenters remarked, "At present I don't see how to make these effects [the weak neutral current event candidates] go away" (Galison, 1987, p. 235).

Galison emphasizes that, within a large experimental group, different members of the group may find different pieces of evidence most convincing. In the Gargamelle weak neutral current experiment, several group members found the single photograph of a neutrino-electron scattering event particularly important, whereas for others the difference in spatial distribution between the observed neutral current candidates and the neutron background was decisive. Galison attributes this, in large part, to differences in experimental traditions, in which scientists develop skill in using certain types of instruments or apparatus. In particle physics, for example, there is the tradition of visual detectors, such as the cloud chamber or the bubble chamber, in contrast to the electronic tradition of Geiger and scintillation counters and spark chambers. Scientists within the visual tradition tend to prefer "golden events" that clearly demonstrate the phenomenon in question, whereas those in the electronic tradition tend to find statistical arguments more persuasive and important than individual events. (For further discussion of this issue see Galison (1997)).

Galison points out that major changes in theory and in experimental practice and instruments do not necessarily occur at the same time. This persistence of experimental results provides continuity across

these conceptual changes. The experiments on the gyromagnetic ratio spanned classical electromagnetism, Bohr's old quantum theory, and the new quantum mechanics of Heisenberg and Schrodinger. Robert Ackermann has offered a similar view in his discussion of scientific instruments.

The advantages of a scientific instrument are that it cannot change theories. Instruments embody theories, to be sure, or we wouldn't have any grasp of the significance of their operation....Instruments create an invariant relationship between their operations and the world, at least when we abstract from the expertise involved in their correct use. When our theories change, we may conceive of the significance of the instrument and the world with which it is interacting differently, and the datum of an instrument may change in significance, but the datum can nonetheless stay the same, and will typically be expected to do so. An instrument reads 2 when exposed to some phenomenon. After a change in theory,\4/ it will continue to show the same reading, even though we may take the reading to be no longer important, or to tell us something other than what we thought originally (Ackermann 1985, p. 33).

Galison also discusses other aspects of the interaction between experiment and theory. Theory may influence what is considered to be a real effect, demanding explanation, and what is considered background. In his discussion of the discovery of the muon, he argues that the calculation of Oppenheimer and Carlson, which showed that showers were to be expected in the passage of electrons through matter, left the penetrating particles, later shown to be muons, as the problem. Prior to their work, physicists thought the showering particles were the problem, whereas the penetrating particles seemed to be understood.

The role of theory as an "enabling theory," one that allows calculation or estimation of the size of the expected effect and also the size of expected backgrounds is also discussed by Galison. (See also (Franklin 1995b) and the discussion of the Stern-Gerlach experiment below). Such a theory can help to determine whether or not an experiment is feasible. He also emphasizes that elimination of background that might simulate or mask an effect is central to the experimental enterprise, and not a peripheral activity. In the case of the weak neutral current experiments the existence of the currents depended crucially on showing that the event candidates could not all be due to neutron background.\5/

There is also a danger that the design of an experiment may preclude observation of a phenomenon. Galison points out that the original design of one of the neutral current experiments, which included a muon trigger would not have allowed the observation of neutral currents. In its original form the experiment was designed to observe charged currents, which produced a high energy muon. Neutral currents do not. Therefore, having a muon trigger precluded their observation. Only after the theoretical importance of the search for neutral currents was emphasized to the experimenters was the trigger changed. Changing the design did not, of course, guarantee that neutral currents would be observed.

Galison also shows that the theoretical presuppositions of the experimenters may enter into the decision to end an experiment and report the result. Einstein and de Haas ended their search for systematic errors when their value for the gyromagnetic ratio of the electron, $g = 1$, agreed with their theoretical model of orbiting electrons. This effect of presuppositions might cause one to be skeptical of both experimental

results and their role in theory evaluation. Galison's history shows, however, that, in this case, the importance of the measurement led to many repetitions of the measurement. This resulted in an agreed upon result that disagreed with theoretical expectations. Scientists do not always find what they are looking for.

B. The Case Against Learning From Experiment

1. Collins and the Experimenters' Regress

Collins, Pickering, and others, have raised objections to the view that experimental results are accepted on the basis of epistemological arguments. They point out that "a sufficiently determined critic can always find a reason to dispute any alleged ‘result’" (MacKenzie 1989, p. 412). Harry Collins, for example, is well known for his skepticism concerning both experimental results and evidence. He develops an argument that he calls the "experimenters' regress" (Collins 1985, chapter 4, pp. 79-111): What scientists take to be a correct result is one obtained with a good, that is, properly functioning, experimental apparatus. But a good experimental apparatus is simply one that gives correct results. Collins claims that there are no formal criteria that one can apply to decide whether or not an experimental apparatus is working properly. In particular, he argues that calibrating an experimental apparatus by using a surrogate signal cannot provide an independent reason for considering the apparatus to be reliable.

In Collins' view the regress is eventually broken by negotiation within the appropriate scientific community, a process driven by factors such as the career, social, and cognitive interests of the scientists, and the perceived utility for future work, but one that is not decided by what we might call epistemological criteria, or reasoned judgment. Thus, Collins concludes that his regress raises serious questions concerning both experimental evidence and its use in the evaluation of scientific hypotheses and theories. Indeed, if no way out of the regress can be found then he has a point.

Collins strongest candidate for an example of the experimenters' regress is presented in his history of the early attempts to detect gravitational radiation, or gravity waves. (For more detailed discussion of this episode see (Collins 1985; 1994; Franklin 1994; 1997a) In this case, the physics community was forced to compare Weber's claims that he had observed gravity waves with the reports from six other experiments that failed to detect them. On the one hand, Collins argues that the decision between these conflicting experimental results could not be made on epistemological or methodological grounds. He claims that the six negative experiments could not legitimately be regarded as replications[\6/] and hence become less impressive. On the other hand, Weber's apparatus, precisely because the experiments used a new type of apparatus to try to detect a hitherto unobserved phenomenon,[\7/] could not be subjected to standard calibration techniques.

The results presented by Weber's critics were not only more numerous, but they had also been carefully cross-checked. The groups had exchanged both data and analysis programs and confirmed their results. The critics had also investigated whether or not their analysis procedure, the use of a linear algorithm,

could account for their failure to observe Weber's reported results. They had used Weber's preferred procedure, a nonlinear algorithm, to analyze their own data, and still found no sign of an effect. They had also calibrated their experimental apparatuses by inserting acoustic pulses of known energy and finding that they could detect a signal. Weber, on the other hand, as well as his critics using his analysis procedure, could not detect such calibration pulses.

There were, in addition, several other serious questions raised about Weber's analysis procedures. These included an admitted programming error that generated spurious coincidences between Weber's two detectors, possible selection bias by Weber, Weber's report of coincidences between two detectors when the data had been taken four hours apart, and whether or not Weber's experimental apparatus could produce the narrow coincidences claimed.

It seems clear that the critics' results were far more credible than Weber's. They had checked their results by independent confirmation, which included the sharing of data and analysis programs. They had also eliminated a plausible source of error, that of the pulses being longer than expected, by analyzing their results using the nonlinear algorithm and by explicitly searching for such long pulses.[\8/] They had also calibrated their apparatuses by injecting pulses of known energy and observing the output.

Contrary to Collins, I believe that the scientific community made a reasoned judgment and rejected Weber's results and accepted those of his critics. Although no formal rules were applied, i.e. if you make four errors, rather than three, your results lack credibility; or if there are five, but not six, conflicting results, your work is still credible; the procedure was reasonable.

Pickering argues that the reasons for accepting results are the future utility of such results for both theoretical and experimental practice and the agreement of such results with the existing community commitments. In discussing the discovery of weak neutral currents, Pickering states,

> Quite simply, particle physicists accepted the existence of the neutral current because they could see how to ply their trade more profitably in a world in which the neutral current was real. (1984b, p. 87)

> Scientific communities tend to reject data that conflict with group commitments and, obversely, to adjust their experimental techniques to tune in on phenomena consistent with those commitments. (1981, p. 236)

The emphasis on future utility and existing commitments is clear. These two criteria do not necessarily agree. For example, there are episodes in the history of science in which more opportunity for future work is provided by the overthrow of existing theory. (See, for example, the history of the overthrow of parity conservation and of CP symmetry discussed below and in (Franklin 1986, Ch. 1, 3)).

2. Pickering on Communal Opportunism and Plastic Resources

Pickering has recently offered a different view of experimental results. In his view the material procedure including the experimental apparatus itself along with setting it up, running it, and monitoring its operation; the theoretical model of that apparatus, and the theoretical model of the phenomena under investigation are all plastic resources that the investigator brings into relations of mutual support. (Pickering 1987; Pickering 1989). He says:

> Achieving such relations of mutual support is, I suggest, the defining characteristic of the successful experiment. (1987, p. 199)

His example is Morpurgo's search for free quarks, or fractional charges of 1/3 *e* or 2/3 *e*, where *e* is the charge of the electron. (See also (Gooding 1992)). Morpurgo used a modern Millikan-type apparatus and initially found a continuous distribution of charge values. Following some tinkering with the apparatus, Morpurgo found that if he separated the capacitor plates he obtained only integral values of charge. "After some theoretical analysis, Morpurgo concluded that he now had his apparatus working properly, and reported his failure to find any evidence for fractional charges" (Pickering 1987, p. 197).

Pickering has made the important point that experimental apparatuses rarely work properly when they are first operated, and that some adjustment, or tinkering, is required before it does. He has also correctly pointed out that the theory of the apparatus and the theory of the phenomena can, and do, form part of the argument for the validity of an experimental result. He has, I believe, overemphasized theory. It was known, from Millikan onwards, that fractional charges, if they exist at all, are very rare in comparison with integral charges. The failure of Morpurgo's apparatus to find integral charges indicated quite strongly that, despite his initial theoretical analysis, it was not an accurate charge measuring device. Only after tinkering, when the apparatus measured integral charges, and thus passed a crucial experimental check, could one legitimately trust its measurements of charge. Although the modified theoretical analysis may have helped to clarify this, it was the experimental check that was crucial. There is more to an experimental apparatus than its theoretical analysis.

3. Critical Responses to Pickering

Ackermann has offered a modification of Pickering's view. He suggests that the experimental apparatus itself is a less plastic resource then either the theoretical model of the apparatus or that of the phenomenon.

> To repeat, changes in A [the apparatus] can often be seen (in real time, without waiting for accommodation by B [the theoretical model of the apparatus]) as improvements, whereas ‘improvements’ in B don't begin to count unless A is actually altered and realizes the improvements conjectured. It's conceivable that this small asymmetry can account, ultimately, for large scale directions of scientific progress and for the objectivity and rationality of those directions. (Ackermann 1991, p. 456)

Hacking (1992) has also offered a more complex version of Pickering's later view. He suggests that the

results of mature laboratory science achieve stability and are self-vindicating when the elements of laboratory science are brought into mutual consistency and support. These are (1) ideas: questions, background knowledge, systematic theory, topical hypotheses, and modeling of the apparatus; (2) things: target, source of modification, detectors, tools, and data generators; and (3) marks and the manipulation of marks: data, data assessment, data reduction, data analysis, and interpretation.

> Stable laboratory science arises when theories and laboratory equipment evolve in such a way that they match each other and are mutually self-vindicating. (1992, p. 56)
>
> We invent devices that produce data and isolate or create phenomena, and a network of different levels of theory is true to these phenomena. Conversely we may in the end count them only as phenomena only when the data can be interpreted by theory. (pp. 57-8)

One might ask whether or not such mutual adjustment between theory and experimental results can always be achieved? What happens when an experimental result is produced by an apparatus on which several of the epistemological strategies, discussed earlier, have been successfully applied, and the result is in disagreement with our theory of the phenomenon? Accepted theories can be refuted. Several examples will be presented below.

Hacking himself worries about what happens when a laboratory science that is true to the phenomena generated in the laboratory, thanks to mutual adjustment and self-vindication, is successfully applied to the world outside the laboratory. Does this argue for the truth of the science. In Hacking's view it does not. If laboratory science does produce happy effects in the "untamed world,... it is not the truth of anything that causes or explains the happy effects" (1992, p. 60).

There is a rather severe disagreement on the reasons for the acceptance of experimental results. For some, like Galison and myself, it is because of epistemological arguments. For others, like Pickering, the reasons are utility for future practice and agreement with existing theoretical commitments. Although the history of science shows that the overthrow of a well-accepted theory leads to an enormous amount of theoretical and experimental work, proponents of this view seem to accept it as unproblematical that it is always agreement with existing theory that has more future utility. Hacking and Pickering also suggest that experimental results are accepted on the basis of the mutual adjustment of elements which includes the theory of the phenomenon.

Nevertheless, everyone seems to agree that a consensus does arise on experimental results. The question then is how are these results used?

II. The Roles of Experiment

A. A Life of Its Own

Although experiment often takes its importance from its relation to theory, Hacking pointed out that it often has a life of its own, independent of theory. He notes the pristine observations of Carolyn Herschel's discovery of comets, William Herschel's work on "radiant heat," and Davy's observation of the gas emitted by algae and the flaring of a taper in that gas. In none of these cases did the experimenter have any theory of the phenomenon under investigation. One may also note the nineteenth century measurements of atomic spectra and the work on the masses and properties on elementary particles during the 1960s. Both of these sequences were conducted without any guidance from theory.

In deciding what experimental investigation to pursue, scientists may very well be influenced by the equipment available and their own ability to use that equipment (McKinney 1992). Thus, when the Mann-O'Neill collaboration was doing high energy physics experiments at the Princeton-Pennsylvania Accelerator during the late 1960s, the sequence of experiments was (1) measurement of the K^+ decay rates, (2) measurement of the K^{+}_{e3} branching ratio and decay spectrum, (3) measurement of the K^{+}_{e2} branching ratio, and (4) measurement of the form factor in K^{+}_{e3} decay. These experiments were performed with basically the same experimental apparatus, but with relatively minor modifications for each particular experiment. By the end of the sequence the experimenters had become quite expert in the use of the apparatus and knowledgeable about the backgrounds and experimental problems. This allowed the group to successfully perform the technically more difficult experiments later in the sequence. We might refer to this as "instrumental loyalty" and the "recycling of expertise" (Franklin 1997b). This meshes nicely with Galison's view of experimental traditions. Scientists, both theorists and experimentalists, tend to pursue experiments and problems in which their training and expertise can be used.

Hacking also remarks on the "noteworthy observations" on Iceland Spar by Bartholin, on diffraction by Hooke and Grimaldi, and on the dispersion of light by Newton. "Now of course Bartholin, Grimaldi, Hooke, and Newton were not mindless empiricists without an ‘idea’ in their heads. They saw what they saw because they were curious, inquisitive, reflective people. They were attempting to form theories. But in all these cases it is clear that the observations preceded any formulation of theory" (Hacking 1983, p. 156). In all of these cases we may say that these were observations waiting for, or perhaps even calling for, a theory. The discovery of any unexpected phenomenon calls for a theoretical explanation.

B. Confirmation and Refutation

Nevertheless several of the important roles of experiment involve its relation to theory. Experiment may confirm a theory, refute a theory, or give hints to the mathematical structure of a theory.

1. The Discovery of Parity Nonconservation: A Crucial Experiment

Let us consider first an episode in which the relation between theory and experiment was clear and straightforward. This was a "crucial" experiment, one that decided unequivocally between two competing theories, or classes of theory. The episode was that of the discovery that parity, mirror-reflection symmetry or left-right symmetry, is not conserved in the weak interactions. (For details of this episode

see Franklin (1986, Ch. 1) and Appendix 1). Experiments showed that in the beta decay of nuclei the number of electrons emitted in the same direction as the nuclear spin was different from the number emitted opoosite to the spin direction. This was a clear demonstartion of parity vilation in the weak interactions.

2. The Discovery of CP Violation: A Persuasive Experiment

After the discovery of parity and charge conjugation nonconservation, and following a suggestion by Landau, physicists considered CP (combined parity and particle-antiparticle symmetry), which was still conserved in the experiments, as the appropriate symmetry. One consequence of this scheme, if CP were conserved, was that the K_1^o meson could decay into two pions, whereas the K_2^o meson could not.[9] Thus, observation of the decay of K_2^o into two pions would indicate CP violation. The decay was observed by a group at Princeton University. Although several alternative explanations were offered, experiments eliminated each of the alternatives leaving only CP violation as an explanation of the experimental result. (For details of this episode see Franklin (1986, Ch. 3) and Appendix 2.)

3. The Discovery of Bose-Einstein Condensation: Confirmation After 70 Years

In both of the episodes discussed previously, those of parity nonconservation and of CP violation, we saw a decision between two competing classes of theories. This episode, the discovery of Bose-Einstein condensation (BEC), illustrates the confirmation of a specific theoretical prediction 70 years after the theoretical prediction was first made. Bose (1924) and Einstein (1924; 1925) predicted that a gas of noninteracting bosonic atoms will, below a certain temperature, suddenly develop a macroscopic population in the lowest energy quantum state.[10] (For details of this episode see Appendix 3.)

C. Complications

In the three episodes discussed in the previous section, the relation between experiment and theory was clear. The experiments gave unequivocal results and there was no ambiguity about what theory was predicting. None of the conclusions reached has since been questioned. Parity and CP symmetry are violated in the weak interactions and Bose-Einstein condensation is an accepted phenomenon. In the practice of science things are often more complex. Experimental results may be in conflict, or may even be incorrect. Theoretical calculations may also be in error or a correct theory may be incorrectly applied. There are even cases in which both experiment and theory are wrong. As noted earlier, science is fallible. In this section I will briefly discuss several episodes which illustrate these complexities.

1. The Fall of the Fifth Force

The episode of the fifth force is the case of a refutation of an hypoothesis, but only after a disagreement between experimental results was resolved. The "Fifth Force" was a proposed modification of Newton's Law of Universal Gravitation. The initial experiments gave conflicting results: one supported the

existence of the Fifth Force whereas the other argued against it. After numerous repetitions of the experiment, the discord was resolved and a consensus reached that the Fifth Force did not exist. (For details of this episode see Appendix 4.)

2. Right Experiment, Wrong Theory: The Stern-Gerlach Experiment

\11/

The Stern-Gerlach experiment was regarded as crucial at the time it was performed, but, in fact, wasn't. In the view of the physics community it decided the issue between two theories, refuting one and supporting the other. In the light of later work, however, the refutation stood, but the confirmation was questionable. In fact, the experimental result posed problems for the theory it had seemingly confirmed. A new theory was proposed and although the Stern-Gerlach result initially also posed problems for the new theory, after a modification of that new theory, the result confirmed it. In a sense, it was crucial after all. It just took some time.

The Stern-Gerlach experiment provides evidence for the existence of electron spin. These experimental results were first published in 1922, although the idea of electron spin wasn't proposed by Goudsmit and Uhlenbeck until 1925 (1925; 1926). One might say that electron spin was discovered before it was invented. (For details of this episode see Appendix 5).

3. Sometimes Refutation Doesn't Work: The Double-Scattering of Electrons

In the last section we saw some of the difficulty inherent in experiment-theory comparison. One is sometimes faced with the question of whether the experimental apparatus satisfies the conditions required by theory, or conversely, whether the appropriate theory is being compared to the experimental result. A case in point is the history of experiments on the double-scattering of electrons by heavy nuclei (Mott scattering) during the 1930s and the relation of these results to Dirac's theory of the electron, an episode in which the question of whether or not the experiment satisfied the conditions of the theoretical calculation was central. Initially, experiments disagreed with Mott's calculation, casting doubt on the underlying Dirac theory. After more than a decade of work, both experimental and theoretical, it was realized that there was a background effect in the experiments that masked the predicted effect. When the background was eliminated experiment and theory agreed. (Appendix 6)

D. Other Roles

1. Evidence for a New Entity: J.J. Thomson and the Electron

Experiment can also provide us with evidence for the existence of the entities involved in our theories. J.J. Thomson's experiments on cathode rays provided grounds for belief in the existence of electrons. (For details of this episode see Appendix 7).

2. The Articulation of Theory: Weak Interactions

Experiment can also help to articulate a theory. Experiments on beta decay during from the 1930s to the 1950s detremined the precise mathematical form of Fermi's theory of beta decay. (For details of this episode see Appendix 8.)

III. Conclusion

In this essay varying views on the nature of experimental results have been presented. Some argue that the acceptance of experimental results is based on epistemological arguments, whereas others base acceptance on future utility, social interests, or agreement with existing community commitments. Everyone agrees , however, that for whatever reasons, a consensus is reached on experimental results. These results then play many important roles in physics and we have examined several of these roles, although certainly not all of them. We have seen experiment deciding between two competing theories, calling for a new theory, confirming a theory, refuting a theory, providing evidence that determined the mathematical form of a theory, and providing evidence for the existence of an elementary particle involved in an accepted theory. We have also seen that experiment has a life of its own, independent of theory. If, as I believe, epistemological procedures provide grounds for reasonable belief in experimental results, then experiment can legitimately play the roles I have discussed and can provide the basis for scientific knowledge.

Notes to Experiment in Physics

* As the late Richard Feynman, one of the leading theoretical physicists of the twentieth century, wrote:

> The principle of science, the definition, almost, is the following: *The test of all knowledge is experiment*. Experiment is the *sole judge* of scientific 'truth'.
> (Feynman, Leighton and Sands 1963, p. 1-1)

In these postmodern times this might seem to be an old-fashioned view, but it is, I believe, correct. Not everyone would agree. As Andy Pickering has remarked,

> ...there is no obligation upon anyone framing a view of the world to take account of what twentieth-century science has to say.
> (Pickering 1984a, p. 413)

1. By valid, I mean that the experimental result has been argued for in the correct way, by use of epistemological strategies such as those discussed below.

2. See Franklin (1986, Ch. 6; and, 1990, Ch. 6) and Franklin and Howson (1984; 1988) for details of these strategies, along with a discussion of how they fit into a Bayesian philosophy of science

3. As Holmes remarked to Watson, "How often have I said to you that when you have eliminated the impossible, whatever remains, *however improbable*, must be the truth." (Conan Doyle 1967, p. 638)

4. It might be useful here to distinguish between the theory of the apparatus and the theory of the phenomenon. Ackermann is talking primarily about the later. It may not always be possible to separate these two theories. The analysis of the data obtained from an instrument may very well involve the theory of the phenomenon, but that doesn't necessarily cast doubt on the validity of the experimental result.

5. For another episode in which the elimination of background was crucial see the discussion of the measurement of the K^+_{e2} branching ratio in (Franklin 1990, pp. 115-31).

6. Collins offers two arguments concerning the difficulty, if not the virtual impossibility of replication. The first is philosophical. What does it mean to replicate an experiment? In what way is the replication similar to the original experiment? A rough and ready answer is that the replication measures the same physical quantity. Whether or not it, in fact, does so can, I believe, be argued for on reasonable grounds, as discussed earlier.

Collins' second argument is pragmatic. This is the fact that in practice it is often difficult to get an experimental apparatus, even one known to be similar to another, to work properly. Collins illustrates

this with his account of Harrison's attempts to construct two versions of a TEA leaser (Transverse Excited Atmospheric) (Collins 1985, pp. 51-78). Despite the fact that Harrison had previous experience with such lasers, and had excellent contacts with experts in the field, he had great difficulty in building the lasers. Hence the difficulty of replication.

Ultimately Harrison found errors in his apparatus and once these were corrected the lasers operated properly. As Collins admits, "...in the case of the TEA laser the circle was readily broken. The ability of the laser to vaporize concrete, or whatever, comprised a universally agreed criterion of experimental quality. There was never any doubt that the laser ought to be able to work and never any doubt about when one was working and when it was not." (Collins 1985, p. 84)

Although Collins seems to regard Harrison's problems with replication as casting light on the episode of gravity waves, as support for the experimenters' regress, and as casting doubt on experimental evidence in general, it really doesn't work. As Collins admits (see quote in last paragraph), the replication was clearly demonstrable. One may wonder what role Collins thinks this episode plays in his argument.

7. In more detailed discussions of this episode, Franklin (1994, 1997a), I argued that the gravity wave experiment is not at all typical of physics experiments. In most experiments, as illustrated in those essays, the adequacy of the surrogate signal used in the calibration of the experimental apparatus is clear and unproblematical. In cases where it is questionable considerable effort is devoted to establishing the adequacy of that surrogate signal. Although Collins has chosen an atypical example I believe that the questions he raises about calibration in general and about this particular episode of gravity wave experiments should be answered.

8. Weber had suggested that the actual gravity wave pulses were longer that expected, and that the nonlinear analysis algorithm was more efficient at detecting such pulses.

9. The K_1^o and K_2^o mesons were elementary particles with the same charge, mass, and intinsic spin. They did, however, differ with respect to the CP operator. The K_1^o and K_2^o mesons were eigenstates of the CP operator with eigenvalues CP = +1 and -1, respectively.

10. Bose's paper had originally been rejected by the *Philosophical Magazine*. He then sent it, in English, to Einstein with a request that if Einstein thought the paper merited publication that he would arrange for publication in the *Zeitschrift fur Physik*. Einstein personally translated the paper and submitted it to the *Zeitschrift fur Physik*, adding a translator's note, "In my opinion, Bose's derivation of the Planck formula constitutes an important advance. The method used here also yields the quantum theory of the ideal gas, as I shall discuss elsewhere in more detail" (Pais 1982, p. 423). This discussion appeared in Einstein's own papers of 1924 and 1925. For details see Pais (1982, Ch. 23).

11. This section is based on the accounts given by Weinert (1995) and by Mehra and Rechenberg (1982). Translations from the German were provided by these authors and are indicated by initials in the text.

Notes to Appendix 2

1. I surveyed eighty such theoretical papers. Sixty accepted the Princeton result as evidence for either CP violation or apparent CP violation. Even those that offered alternative explanations of the result were not necessarily indications that the authors did not accept CP violation. One should distinguish between interesting speculations and serious suggestions. The latter are characterized by a commitment to their truth. I note that T.D. Lee was author, or co-author, of three of these theoretical papers. Two offered alternative explanations of the Princeton result and one proposed a model that *avoided* CP violation. Lee was not seriously committed to the truth of any of them. Bell and Perring, authors of one of the alternatives, remarked, "Before a more mundane explanation is found *it is amusing to speculate* that it might be a local effect due to the dyssymmetry of the environment, namely the local preponderance of matter over antimatter"(Bell and Perring 1964, p. 348, emphasis added).

2. In the modus tollens if *h* entails *e* then "not *e*" entails not *h*. Duhem and Quine pointed out that it is really *h* and *b,* where *b* is background knowledge and auxiliary hypotheses, that entails *e*. Thus "not *e*" entails "*h*" or "*b*" and one doesn't know where to place the blame.

Notes to Appendix 3

1. Bose's paper had originally been rejected by the *Philosophical Magazine*. He then sent it, in English, to Einstein with a request that if Einstein thought the paper merited publication that he would arrange for publication in the *Zeitschrift fur Physik*. Einstein personally translated the paper and submitted it to the *Zeitschrift fur Physik*, adding a translator's note, "In my opinion, Bose's derivation of the Planck formula constitutes an important advance. The method used here also yields the quantum theory of the ideal gas, as I shall discuss elsewhere in more detail" (Pais 1982, p. 423). This discussion appeared in Einstein's own papers of 1924 and 1925. For details see Pais (1982, Ch. 23).

2. One difficulty with using rubidium is that at very low temperatures rubidium should be a solid. (In fact, rubidium is a solid at room temperature). Wieman, Cornell and their collaborators avoided this difficulty by creating a system that does not reach a true equilibrium. The vapor sample created equilibrates to a thermal distribution as a spin polarized gas, but takes a very long time to reach its true equilibrium state as a solid. At the low temperatures and density of the experiment the rubidium remains as a metastable super-saturated vapor for a long time.

Notes to Appendix 4

1. The original Eötvös experiment was designed to measure the ratio of the gravitational mass to the inertial mass of different substances. Eötvös found the ratio to be one, to within approximately one part in a million. Fischbach and his collaborators reanalyzed Eötvös' data and found a composition dependent effect, which they interpreted as evidence for a Fifth Force.

2. It is a fact of experimental life that experiments rarely work when they are initially turned on and that experimental results can be wrong, even if there is no apparent error. It is not necessary to know the exact source of an error in order to discount or to distrust a particular experimental result. Its disagreement with numerous other results can, I believe, be sufficient.

Notes to Appendix 6

1. Rupp's withdrawal included a note from a psychiatrist stating that Rupp had suffered from a mental illness and could not distinguish between fantasy and reality.

2. The problem with the hydrogen spectrum was not solved until the later discovery of the anomalous magnetic moment of the electron in the 1950s.

Notes to Appendix 7

1. Morrison (1990) has argued that manipulability is not sufficient to establish belief in an entity. She discusses particle physics experiments in which particle beams were viewed not only as particles, but also as beams of quarks, the constituents of the particles, even though the physicists involved had no belief in the existence of quarks. Although I believe that Morrison's argument is correct in this particular case, I do think that manipulability can, and often does, give us good reason to believe in an entity. See, for example, the discussion of the microscope in Hacking (1983).

2. Millikan, for example, used the properties of electrons emitted in the photoelectric effect to measure *h*, Planck's constant. Stern and Gerlach, as discussed below, used the properties of the electron to investigate spatial quantization, and also discovered evidence for electron spin.

3. For more details of this episode, including a discussion of other early twentieth century experiments, see (Franklin 1997c).

4. In Cartwright's discussion of the electron track in the cloud chamber, for example, she can identify the track as an electron track rather than as a proton track only because she has made an implicit commitment to the law of ionization for charged particles, and it's dependence on the mass and velocity of the particles.

5. Thomson also demonstrated the magnetic deflection of cathode rays in a separate experiment.

6. Thomson actually investigated the conductivity of the gas in the tube under varying pressure conditions. See Thomson (1897, pp. 298-300).

7. I shall return to this when I discuss Thomson's measurement of *e/m* for the electron.

8. Thomson's argument is the "duck argument." If it looks like a duck, quacks like a duck, and waddles like a duck, then we have good reason to believe that it is a duck. One need only reconstitute the argument using "it" as cathode rays and negatively charged particles as ducks.

9. Thomson actually used two different methods to determine the charge to mass ratio. The other method used the total charge carried by a beam of cathode rays in a fixed period of time, the total energy carried by the beam in that sane time, and the radius of curvature of the particles in a known magnetic field. Thomson regarded the method discussed in the text as more reliable and this is the method shown in most modern physics textbooks.

10. Not everything Thomson concluded is in agreement with modern views. Although he believed that the electron was a constituent of atoms, he thought that it was the primordial atom from which all atoms were constructed, similar to Prout's view that all atoms were constructed from hydrogen atoms. He also suggested that the charge on the electron might be larger than that of the hydrogen ion.

Notes to Appendix 8

1. The conservation of momentum also requires that the electron and proton have equal and opposite momenta, for a neutron decay at rest. They will be emitted in opposite directions.

2. Pauli's suggestion was first made in a December 4, 1930 letter to the radioactive group at a regional meeting in Tuebingen.

> Dear Radioactive Ladies and Gentlemen:
>
> I beg you to receive graciously the bearer of this letter who will report to you in detail how I have hit on a desperate was to escape from the problems of the "wrong" statistics of the N and Li^6 nuclei and of the continuous beta spectrum in order to save the "even-odd" rule of statistics and the law of conservation of energy. Namely the possibility that electrically neutral particles, which I would like to call neutrons [the particle we call the neutron, which is about the same mass as the proton, was discovered in 1932 by Chadwick. Pauli's "neutron" is our "neutrino."] might exist inside nuclei; these would have spin 1/2, would obey the exclusion principle, and would in addition duffer from photons through the fact that they would not travel at the speed of light. The mass of the neutron ought to be about the same order of magnitude as the electron mass, and in any case could not be greater than 0.01 proton masses. The continuous beta spectrum would then become understandable by assuming that in beta decay a neutron is always emitted along with the electron, in such a way that the sum of the energies of the neutron and electron is a constant.

> Now, the question is, what forces act on the neutron? The most likely model for the neutron seems to me, on wave mechanical grounds, to be the assumption that the motionless neutron is a magnetic dipole with a certain magnetic moment μ (the bearer of this letter can supply details). The experiments demand that the ionizing power of such a neutron cannot exceed that of a gamma ray, and therefore μ probably cannot be greater than $e(10^{-13}\text{cm})$. [*e* is the charge of the electron].
>
> At the moment I do not dare to publish anything about this idea, so I first turn trustingly to you, dear radioactive friends, with the question: how could such a neutron be experimentally identified if it possessed about the same penetrating power as a gamma ray or perhaps 10 times greater penetrating power?
>
> I admit that my way out may look rather improbable at first since if the neutron existed it would have been seen long ago. But nothing ventured, nothing gained. The gravity of the situation with the continuous beta spectrum was illuminated by a remark by my distinguished predecessor in office, Mr. DeBye, who recently said to me in Brussels, "Oh, that's a problem like the new taxes; one had best not think about it at all." So one ought to discuss seriously any way that may lead to salvation. Well, dear radioactive friends, weigh it and pass sentence! Unfortunately, I cannot appear personally in Tubingen, for I cannot get away from Zurich on account of a ball which is held here on the night of December 6-7. With best regards to you and to Mr. Baek,
>
> Your most obedient servant,
> W. Pauli
>
> (Quoted in Ford 1968, p. 849.)

This was a serious suggestion and although Pauli did not get all the properties of the neutrino right his suggestion was the basis of further work.

3. With a three-body decay the electron and the proton also didn't have to come off back to back. This observation was not made until the late 1930s. Assigning the neutrino a spin, intrinsic angular momentum, of h/4 also preserved the law of conservation of angular momentum.

4. The actual history is more complex. For a time, an alternative theory of decay, proposed by Konopinski and Uhlenbeck (1935) was better supported by the experimental evidence than was Fermi's theory. It was subsequently shown that both the experimental results and the theoretical calculations were wrong and that Fermi's theory was , in fact, supported by the evidence. For details see (Franklin 1990).

5. Allowed transitions are those for which both the electron and neutrino wavefunctions could be considered constant over nuclear dimensions. Forbidden transitions are those that included higher order terms in the perturbation series expansion of the matrix element.

6. I have been unable to find a published reference to this measurement. It is cited as a private communication in the literature.

7. In a post-deadline paper presented at the January 1958 meeting of the American Physical Society, Rustad and Ruby suggested that their earlier result might be wrong. There are no abstracts of post-deadline papers, but the talk was cited in the literature. Ruby remembers the tone of the paper as *mea culpa* (private communication).

Appendix 1: The Discovery of Parity Nonconservation

Let us consider first an episode in which the relation between theory and experiment was clear and straightforward. This was a "crucial" experiment, one that decided unequivocally between two competing theories, or classes of theory. The episode was that of the discovery that parity, mirror-reflection symmetry or left-right symmetry, is not conserved in the weak interactions. (For details of this episode see Franklin (1986, Ch. 1)). Parity conservation was a well-established and strongly-believed principle of physics. As students of introductory physics learn, if we wish to determine the magnetic force between two currents we first determine the direction of the magnetic field due to the first current, and then determine the force exerted on the second current by that field. We use two Right-Hand Rules. We get exactly the same answer, however, if we use two Left-Hand Rules, This is left-right symmetry, or parity conservation, in electromagnetism.

In the early 1950s physicists were faced with a problem known as the "τ-θ" puzzle. Based on one set of criteria, that of mass and lifetime, two elementary particles (the tau and the theta) appeared to be the same, whereas on another set of criteria, that of spin and intrinsic parity, they appeared to be different. T.D. Lee and C.N. Yang (1956) realized that the problem would be solved, and that the two particles would be different decay modes of the same particle, if parity were not conserved in the decay of the particles, a weak interaction. They examined the evidence for parity conservation and found, to their surprise, that although there was strong evidence that parity was conserved in the strong (nuclear) and electromagnetic interactions, there was, in fact, no supporting evidence that it was conserved in the weak interaction. It had never been tested.

Lee and Yang suggested several experiments that would test their hypothesis that parity was not conserved in the weak interactions. One was the β decay of oriented nuclei (Figure 1). Consider a collection of radioactive nuclei, all of whose spins point in the same direction. Suppose also that the electron given off in the radioactive decay of the nucleus is always emitted in a direction opposite to the spin of the nucleus In the mirror the electron is emitted in the same direction as the spin. The mirror image of the decay is different from the real decay. This would violate parity conservation, or mirror symmetry. Parity would be conserved only if, in the decay of a collection of nuclei, equal numbers of electrons were emitted in both directions. This was the experimental test performed by C.S. Wu and her collaborators (1957). They aligned Cobalt^{60} nuclei and counted the number of decay electrons in the two directions, along the nuclear spin and opposite to the spin. Their results are shown in Figure 2 and indicate clearly that more electrons are emitted opposite to the spin than along the spin. Parity is not conserved.

Two other experiments, reported at the same time, on the sequential decay pi meson decays to mu meson decays to electron also showed parity nonconservation (Friedman and Telegdi 1957; Garwin, Lederman and Weinrich 1957). These three experiments decided between two classes of theories--that is, between those theories that conserve parity and those that do not. They refuted the theories in which parity was conserved and supported or confirmed those in which it wasn't. These experiments also demonstrated that charge conjugation, or particle-antiparticle, symmetry was violated in the weak interactions and called for a new theory of decay and the weak interactions. It is fair to say that when a physicist learned the results of these experiments they were convinced that parity was not conserved in the weak interactions.

Supplement to Experiment in Physics

Appendix 2: The Discovery of CP Violation: A Persuasive Experiment

A group at Princeton University, led by Cronin and Fitch, decided to test CP conservation. The experimenters were quite aware of the relevance of their experiment to the question of CP violation, but they did not expect to observe it. As Val Fitch, one of the group leaders remarked, "Not many of our colleagues would have given credit for studying CP invariance, but we did so anyway" (Fitch 1981, p. 991). A preliminary estimate indicated that the CP phase of the experiment would detect about 7500 K_2^o decays and thus reduce the limit on CP violation from the then current limit of 1/300 (0.3%) to 1/7500 (For details of this episode see Franklin (1986, Ch. 3)).

The experimental beam contained only K_2^o mesons. (The K_1^o meson has a much shorter lifetime than the K_2^o meson, so that if we start with a beam containing both types of particles, after a time only the K_2^o mesons will remain). The experimental apparatus detected two charged particles from the decay of the K_2^o meson. The vector momentum of each of the two decay products from the K_2^o beam and the invariant mass m^* were computed assuming that each product had the mass of a pion:

$$m^* = [(E_1 + E_2)^2 - (\mathbf{p}_1 + \mathbf{p}_2)^2]^{½},$$

where E and **p** are the energy and vector momenta of the pions, respectively. If both particles were indeed pions from K_2^o decay, m^* would equal the K_2^o mass. The experimenters also computed the vector sum of the two momenta and the angle between this sum and the direction of the K_2^o beam. This angle should be zero for two-body decays, but not, in general, for three-body decays.

This was exactly what the Princeton group observed (Christenson et al. 1964). As seen clearly in Figure 3, there is a peak at the K^o mass, 498 MeV/c^2, for events with cos(θ) greater than 0.9999 (cos(θ) approximately equal to 1 means θ is approximately equal to 0). No such peak is seen in the mass regions just above or just below the K^o mass. The experimenters reported a total of 45 ± 9 two-pion K_2^o decays out of a total of 22,700 K_2^o decays. This was a branching ratio of (1.95 ± 0.2) x 10^{-3}, or approximately 0.2 percent.

The most obvious interpretation of the Princeton result was that CP symmetry was violated. This was the view taken in three out of four theoretical papers written during the period immediately following the

report of that result. The Princeton result had persuaded most of the physics community that CP symmetry was violated. The remaining theoretical papers offered alternative explanations.\1/ These alternatives relied on one or more of three arguments: (1) the Princeton results are caused by a CP asymmetry (the local preponderance of matter over antimatter) in the environment of the experiment, (2) K_2^o decay into two pions does not necessarily imply CP violation, and (3) the Princeton observations did not arise from two-pion K_2^o decay. This last argument can divided into the assertions that (3a) the decaying particle was not a K_2^o meson, (3b) the decay products were not pions, and (3c) another unobserved particle was emitted in the decay. Included in these alternatives were three suggestions that cast doubt on well-supported fundamental assumptions of modern physics. These were: (1) pions are not bosons, (2) the principle of superposition in quantum mechanics is violated, and (3) the exponential decay law fails. Although by the end of 1967 all of these alternatives had been experimentally tested and found wanting, the majority of the physics community had accepted CP violation by the end of 1965, even though all the tests had not yet been completed. As Prentki, a theoretical particle physicist, remarked, this was because in some cases "the price one has to pay in order to save CP becomes extremely high," and because other alternatives were "even more unpleasant"(Prentki 1965).

This is an example of what one might call a pragmatic solution to the Duhem-Quine problem.\2/ The alternative explanations and the auxiliary hypotheses were refuted, leaving CP violation unprotected. One might worry that other plausible alternatives were never suggested or considered. This is not a serious problem in the actual practice of physics. No fewer than ten alternative explanations of the Princeton result were offered, and not all of them were very plausible. Had others been suggested they, too, would have been considered by the physics community. Consider the model of Nishijima and Saffouri (1965). They explained two-pion K_2^o decay by the existence of a "shadow" universe in touch with our "real" universe only through the weak interactions. They attributed to the two pion decay observed to the decay of the $K^{o'}$ from the shadow universe. This implausible model was not merely considered, it was also experimentally tested. Everett (1965) noted that if the $K^{o'}$, the shadow K^o postulated by Nishijima and Saffouri existed, then a shadow pion should also exist, and the decays of the K^+ into a positive pion and a neutral pion and of the K^+ into a positive pion and a neutral shadow pion and should occur with equal rates. The presence of the shadow pion could be detected by measuring the ordinary K^+ branching ratio in two different experiments, one in which the neutral pion was detected and one in which it was not. If the shadow pion existed the two measurements would differ. They didn't. There was no shadow pion and thus, no $K^{o'}$.

What was the difference between the episodes of parity nonconservation and CP violation. In the former parity nonconservation was immediately accepted. No alternative explanations were offered. There was a convincing and decisive set of experiments. In the latter at least ten alternatives were proposed, and although CP violation was accepted rather quickly, the alternatives were tested. In both cases there are only two classes of theories, those that conserve parity or CP, and those that do not. The difference lies in the length and complexity of the derivation linking the hypothesis to the experimental result, or to the number of auxiliary hypotheses required for the derivation. In the case of parity nonconservation the experiment could be seen by inspection to violate mirror symmetry (See Figure 1). In the CP episode

what was observed was K_2^o decay into two pions. In order to connect this observation to CP conservation one had to assume (1) the principle of superposition, (2) that the exponential decay law held to 300 lifetimes, (3) that the decay particles were both "real" pions and that pions were bosons, (4) that no other particle was emitted in the decay, (5) that no other similar particle was produced, and (6) that there were no external conditions present that might regenerate K_1^o mesons. It was these auxiliary assumptions that were tested and eliminated as alternative explanations by subsequent experiments.

The discovery of CP violation called for a theoretical explanation, a call that is still unanswered.

Appendix 3: The Discovery of Bose-Einstein Condensation: Confirmation After 70 Years

In both of the episodes discussed previously, those of parity nonconservation and of CP violation, we saw a decision between two competing classes of theories. This episode, the discovery of Bose-Einstein condensation (BEC), illustrates the confirmation of a specific theoretical prediction 70 years after the theoretical prediction was first made. Bose (1924) and Einstein (1924; 1925) predicted that a gas of noninteracting bosonic atoms will, below a certain temperature, suddenly develop a macroscopic population in the lowest energy quantum state.\1/ An interesting aspect of this episode is that the phenomenon in question had never been observed previously. This raises an interesting epistemological problem. How do you know you have observed something that has never been seen before?

Elementary particles can be divided onto two classes: bosons with integral spin (0, 1 ,2, ...), and fermions with half-integral spin (1/2, 3/2, 5/2, ...). Fermions, such as electrons obey the Pauli Exclusion Principle. Two fermions cannot be in the same quantum mechanical state. This explains the shell structure of electrons in atoms and the periodic table. On the other hand, any number of bosons can occupy the same state. At sufficiently low temperatures, when thermal motions are very small, there is a strong tendency for a group of bosons to all go into the same state.

The experiment that first demonstrated the existence of BEC was done by Carl Wieman, Eric Cornell, and their collaborators (Anderson et al. 1995). The experimental apparatus is shown is Figure 4. In outline the experiment was as follows. A sample of ^{87}Rb atoms was cooled in a magneto-optical trap. It was then loaded into a magnetic trap and further cooled by evaporation. The condensate was formed and the trap removed, allowing the condensate to expand. The expanded condensate was illuminated with laser light and the resulting shadow of the cloud was imaged, digitized, and stored.\2/

The experimental results are shown in Figures 5 - 7. Figure 5 shows the velocity distribution of the rubidium gas cloud (a) just before the appearance of the condensate, (b) just after, and (c) after further evaporation of the cloud has left a sample of nearly pure condensate. This figure also shows the spatial distribution of the gas. Although the measurement process destroyed the condensate sample, the entire process can be repeated so that one can measure the cloud at different stages. Figure 6 shows the peak density of the gas as a function of the RF frequency used to excite the atoms into a non-confined state and to assist the cooling by evaporation). There is a sharp increase in density at a frequency of 4.23 MHz. This indicates the appearance of Bose-Einstein condensation. As the sample is further cooled one expects to observe a two-component cloud with a dense central condensate surrounded by a diffuse non-

condensate. This is seen clearly in both Figures 5 and 7. Figure 7 shows horizontal sections of the rubidium cloud. At 4.71 MHz, above the transition temperature, one sees only a broad thermal distribution. Beginning at 4.23 MHz one sees the appearance of a sharp central peak, the Bose-Einstein condensate, above the thermal distribution. At 4.11 MHz the cloud is almost a pure condensate.

There are three clear indications of the presence of Bose-Einstein condensation: (1) the velocity distribution of the gas shows two distinct components, (2) the sudden increase in density as the temperature decreases, and (3) the elliptical shape of the velocity distribution (Figure 5). The velocity distribution should be elliptical because for the harmonic trap used, the force in the z direction was eight times larger than in the x and y directions. No phenomenon other than Bose-Einstein condensation could plausibly explain these results

This result was sufficiently credible that Keith Burnett, an atomic physicist at Oxford University remarked, in the same issue of *Science* in which Wieman and Cornell reported their result, "In short, they have observed the phenomenon called Bose-Einstein condensation (BEC) in a gas of atoms for the first time. The term Holy Grail seems quite appropriate given the singular importance of this discovery" (Burnett 1995, p. 182).

A theoretical prediction had been confirmed after 70 years.

Appendix 4: The Fall of the Fifth Force

In this episode we will examine a case of the refutation of a hypothesis, but only after a disagreement between experimental results was resolved. The "Fifth Force" was a proposed modification of Newton's Law of Universal Gravitation. The initial experiments gave conflicting results: one supported the existence of the Fifth Force whereas the other regued against it. After numerous repetitions of the experiment, the discord was resolved and a consensus reached that the Fifth Force Did not exist. A reanalysis of the original Eötvös experiment[\1/] by Fischbach and his collaborators (1986) had shown a suggestive deviation from the law of gravity. The Fifth Force, in contrast to the famous Galileo experiment, depended on the composition of the objects. Thus, the Fifth Force between a copper mass and an aluminum mass would differ from that between a copper mass and a lead mass. Fischbach and collaborators also suggested modifying the gravitational potential between two masses from

$$V = -Gm_1m_2/r$$

to

$$V = -Gm_1m_2/r\ [1 + (\alpha)e^{-r/\lambda}],$$

where the second term gives the Fifth Force with strength α and range λ. The reanalysis also suggested that α was approximately 0.01 and λ was approximately 100m. (For details of this episode see (Franklin 1993)).

In this episode, we have a hitherto unobserved phenomenon along with discordant experimental results. The first two experiments on the Fifth Force gave contradictory answers. One experiment supported the existence of the Fifth Force, whereas the other found no evidence for it. The first experiment, that of Peter Thieberger (1987a) looked for a composition-dependent force using a new type of experimental apparatus, which measured the differential acceleration between copper and water. The experiment was conducted near the edge of the Palisades cliff in New Jersey to enhance the effect of an intermediate-range force. The experimental apparatus is shown in Figure 8. The horizontal acceleration of the copper sphere relative to the water can be determined by measuring the steady-state velocity of the sphere and applying Stokes' law for motion in a resistive medium. Thieberger's results are shown in Figure 9. The sphere clearly has a velocity, indicating the presence of a force. Thieberger concluded, "The present results are compatible with the existence of a medium-range, substance-dependent force" (p. 1068).

The second experiment, by the whimsically named Eöt-Wash group, was also designed to look for a substance-dependent, intermediate range force (Raab 1987; Stubbs et al. 1987). The apparatus was located on a hillside on the University of Washington campus, in Seattle (Figure 10). If the hill attracted the copper and beryllium bodies differently, then the torsion pendulum would experience a net torque. This torque could be observed by measuring shifts in the equilibrium angle of the torsion pendulum as the pendulum was moved relative to a fixed geophysical point. Their experimental results are shown in Figure 11. The theoretical curves were calculated with the assumed values of 0.01 and 100m, for the Fifth Force parameters α and λ, respectively. These were the best values for the parameters at the time. There is no evidence for such a Fifth Force in this experiment.

The problem was, however, that both experiments appeared to be carefully done, with no apparent mistakes in either experiment. Ultimately, the discord between Thieberger's result and that of the Eöt-Wash group was resolved by an overwhelming preponderance of evidence in favor of the Eöt-Wash result (The issue was actually more complex. There were also discordant results on the distance dependence of the Fifth Force. For details see Franklin (1993; 1995a)). The subsequent history is an illustration of one way in which the scientific community deals with conflicting experimental evidence. Rather than making an immediate decision as to which were the valid results, this seemed extremely difficult to do on methodological or epistemological grounds, the community chose to await further measurements and analysis before coming to any conclusion about the evidence. The torsion-balance experiments of Eöt-Wash were repeated by others including (Cowsik et al. 1988; Fitch, Isaila and Palmer 1988; Adelberger 1989; Bennett 1989; Newman, Graham and Nelson 1989; Stubbs et al. 1989; Cowsik et al. 1990; Nelson, Graham and Newman 1990). These repetitions, in different locations and using different substances, gave consistently negative results. In addition, Bizzeti and collaborators (1989a; 1989b), using a float apparatus similar to that of Thieberger, also obtained results showing no evidence of a Fifth Force. There is, in fact, no explanation of either Thieberger's original, presumably incorrect, results. The scientific community has chosen, I believe quite reasonably, to regard the preponderance of negative results as conclusive.[\2/] Experiment had shown that there is no Fifth Force.

Appendix 5: Right Experiment, Wrong Theory: The Stern-Gerlach Experiment

From the time of Ampere onward, molecular currents were regarded as giving rise to magnetic moments. In the nuclear model of the atom the electron orbits the nucleus. This circular current results in a magnetic moment. The atom behaves as if it were a tiny magnet. In the Stern-Gerlach experiment a beam of silver atoms passed through an inhomogeneous magnetic field (Figure 12). In Larmor's classical theory there was no preferential direction for the direction of the magnetic moment and so one predicted that the beam of silver atoms would show a maximum in the center of the beam. In Sommerfeld's quantum theory an atom in a state with angular momentum equal to one (L = 1) would have a magnetic moment with two components relative to the direction of the magnetic field, $\pm eh/4m_e$. (Bohr had argued that only two spatial components were allowed). In an inhomogeneous magnetic field, H, the force on the magnetic moment μ will be μ_z x (Gradient of the magnetic field in the z direction), where $\mu_z = \pm eh/4m_e$, where e is the charge of the electron, m_e is its mass, h is Planck's constant, and z is the field direction. Thus, depending on the orientation of the magnetic moment relative to the magnetic field there will be either an attractive or repulsive force and the beam will split into two components, exhibiting spatial quantization. There will be a minimum at the center of the beam. "According to quantum theory μ_z can only be $\pm (e/2m_e)(h/2\pi)$. In this case the spot on the receiving plate will therefore be split into two, each of them having the same size but half the intensity of the original spot" (Stern 1921, p. 252, JM) This difference in prediction between the Larmor and Sommerfeld theories was what Stern and Gerlach planned to use to distinguish between the two theories. Stern remarked that "the experiment, if it can be carried out, (will result) in a clear-cut decision between the quantum-theoretical and the classical view" (Stern 1921, FW).

Sommerfeld's theory also acted as an enabling theory for the experiment. It provided an estimate of the size of the magnetic moment of the atoms so that Stern could begin calculations to see if the experiment was feasible. Stern calculated, for example, that a magnetic field gradient of 10^4 Gauss per centimeter would be sufficient to produce deflections that would give detectable separations of the beam components. He asked Gerlach if he could produce such a gradient. Gerlach responded affirmatively, and said he could do even better. The experiment seemed feasible. A sketch of the apparatus is shown in Figure 12. The silver atoms pass through the inhomogeneous magnetic field. If the beam is spatially quantized, as Sommerfeld predicted, two spots should be observed on the screen. (The sketch shows the beam splitting into three components, which would be expected in modern quantum theory for an atom with angular momentum equal to one). I note that Sommerfeld's theory was incorrect, illustrating the point that an enabling theory need not be correct to be useful.

A preliminary result reported by Stern and Gerlach did not show splitting of the beam into components. It did, however, show a broadened beam spot. They concluded that although they had not demonstrated spatial quantization, they had provided "evidence that the silver atom possesses a magnetic moment." Stern and Gerlach made improvements in the apparatus, particularly in replacing a round beam slit by a rectangular one that gave a much higher intensity. The results are shown in Figure 13 (Gerlach and Stern 1922a). There is an intensity minimum in the center of the pattern, and the separation of the beam into two components is clearly seen. This result seemed to confirm Sommerfeld's quantum-theoretical prediction of spatial quantization. Pauli, a notoriously skeptical physicist, remarked, "Hopefully now even the incredulous Stern will be convinced about directional quantization" (in a letter from Pauli to Gerlach 17 February 1922). Pauli's view was shared by the physics community. Nevertheless the Stern-Gerlach result posed a problem for the Bohr-Sommerfeld theory of the atom. Stern and Gerlach had assumed that the silver atoms were in an angular momentum state with angular momentum equal to one (L = 1). In fact, the atoms are in an L = 0 state, for which no splitting of the beam would be expected in either the classical or the quantum theory. Stern and Gerlach had not considered this possibility. Had they done so they might not have done the experiment. The later, or new, quantum theory developed by Heisenberg, Schrodinger, and others, predicted that for an L = 1 state the beam should split into three components as shown in Figure 12. The magnetic moment of the atom would be either 0 or ± eh/(4π x m). Thus, if the silver atoms were in an L = 1 state as Stern and Gerlach had assumed, their result, showing two beam components, also posed a problem for the new quantum theory. This was solved when Uhlenbeck and Goudsmit (1925, 1926) proposed that the electron had an intrinsic angular momentum or spin equal to h/4π. This is analogous to the earth having orbital angular momentum about the sun and also an intrinsic angular momentum due to its rotation on its own axis. In an atom the electron will have a total angular momentum **J** = **L** + **S**, where **L** is the orbital angular momentum and **S** is the spin of the electron. For silver atoms in an L = 0 state the electron would have only its spin angular momentum and one would expect the beam to split into two components. Goudsmit and Uhlenbeck suggested the idea of electron spin to explain features in atomic spectra such as the anomalous Zeeman effect, the splitting of spectral lines in a magnetic field into more components than could be accommodated by the Bohr-Sommerfeld theory of the atom. Although the Stern-Gerlach results were known, and would certainly have provided strong support for the idea of electron spin, Goudsmit and Uhlenbeck made no mention of the result.

The Stern-Gerlach experiment was initially regarded as a crucial test between the classical theory of the atom and the Bohr-Sommerfeld theory. In a sense it was, because it showed clearly that spatial quantization existed, a phenomenon that could be accommodated only within a quantum mechanical theory. It decided between the two classes of theories, the classical and the quantum mechanical. With respect to the particular quantum theory of Bohr and Sommerfeld, however, it wasn't crucial, although it was regarded as such at the time, because that theory predicted no splitting for a beam of silver atoms in the ground state (L = 0). The theory had been wrongly applied. The two-component result was also problematic for the new quantum theory, which also predicts no splitting for an angular momentum zero state and three components for an L = 1 state. Only after the suggestion of electron spin did the Stern-Gerlach result confirm the new theory.

Although the interpretation of the experimental result was incorrect for a time, the result itself remained quite robust through the theory change from the old to the new quantum theory. It is important to remember that experimental results do not change when accepted theory changes, although certainly, as we have seen, their interpretation may change. Gerlach and Stern emphasized this point themselves.

Apart from any theory, it can be stated, as a pure result of the experiment, and as far as the exactitude of our experiments allows us to say so, that silver atoms in a magnetic field have only *two discrete* values of the component of the magnetic moment in the direction of the field strength; both have the same absolute value with each half of the atoms having a positive and a negative sign respectively (Gerlach and Stern 1924, pp. 690-691, FW)

Experimental results, as well as experiments, also have a life of their own, independent of theory.

Supplement to Experiment in Physics

Appendix 6: Sometimes Refutation Doesn't Work: The Double-Scattering of Electrons

In 1929, Mott (1929, and later 1931, 1932) calculated, on the basis of Dirac's theory of the electron, that there would be a forward-backward asymmetry of approximately 10% in the double scattering of electrons from heavy nuclei. Mott clearly specified the conditions that would have to be satisfied in order to observe this effect. One had to double scatter relativistic electrons at large angles (90º) from heavy nuclei (most calculations assumed a nuclear charge Z approximately 80). The first scatter would polarize the electrons and the second scatter would analyze the produced polarization, giving rise to an asymmetry.

The earliest experiment that discussed Mott's calculation was performed by Chase (1929). He observed a 4% asymmetry in the double scattering of electrons but attributed it to a difference in the path that the electrons followed. His subsequent experiment (Chase 1930) reported a 1.5% effect, and this time did attribute it to Mott scattering. Most experiments during the early 1930s, showed no polarization effects, although some of them did not satisfy the conditions for Mott scattering (For details see Franklin (1986, Ch. 2)). The sole positive results were provided by experiments done by Rupp (1929; 1930a; 1930b; 1931; 1932a; 1932b; 1932c). Rupp's 1932 experiment first scattered electrons at 90º from a gold foil, followed by a 90º scatter from a gold wire. He found a 3-4% asymmetry at an electron energy of 130 keV and an asymmetry of 9-10% at 250 keV. These results , although positive, were in quantitative disagreement with Mott's prediction of 15.5% at 127 keV and 14% at 204 keV (Mott 1931). Dymond (1931) also reported a positive result, but one that was five times smaller than the theoretical prediction.

Mott and the rest of the electron-scattering community were quite aware of both the confused nature of the experimental results, and of the apparent discrepancy between experiment and theory. Langstroth (1932) reviewed the situation and commented on the difficulty of experiment-theory comparison when one deals with real, as opposed to ideal, experiments. "In view of the fact that practical conditions may be immensely more complicated than those of Mott's theory, it is not surprising that it does not furnish a guide, even in a qualitative way, to all of the above experiments. This may be due to (a) the fact that a large proportion of the beam scattered from a thick target consists of electrons which have undergone more than one collision, (b) the insufficiency of the theoretical model, (c) the inclusion of extraneous effects in the experimental results" (pp. 566-67).

The situation became even more confused when Dymond(1932) published a detailed account of his experiment, which restated his positive, but discrepant, result. Adding to the confusion was the fact Dymond's experiment seemed to satisfy all the conditions for Mott scattering. Rupp (1934) continued his

work, this time using thallium vapor rather than gold targets, and again found a positive result. G.P. Thomson (1933), on the other hand, found no effect. At approximately the same time Sauter (1933) redid Mott's calculations and obtained identical results. He also considered whether or not screening by atomic electrons could cancel the predicted effect and found that it could not. If things weren't difficult enough, they got worse when Dymond (1934) published a full repudiation of his earlier results. He had found a considerable and variable experimental asymmetry in his apparatus, and concluded that he had not, in fact, observed any polarization effect. Dymond also considered possible reasons for the theory-experiment discrepancy including inelastic, stray, and plural scattering, and nuclear screening and rejected them all. He concluded, "We are driven to the conclusion that the theoretical results are wrong. There is no reason to believe that the work of Mott is incorrect;... It seems not improbable, therefore, that the divergence of theory from experiment has a more deep-seated cause, and that the Dirac wave equation needs modification in order to account successfully for the absence of polarization" (Dymond 1932, p. 666).

G.P. Thomson (1934) also published a comprehensive review of the field. He reported no effects of the type found by Rupp and he found a forward-backward ratio of (0.996 ± 0.01) in comparison to Mott's prediction of 1.15.Thomson also concluded that there was a serious discrepancy between theory and experiment.
